Intrinsic to any patient with complete transposition of the great arteries, but particularly in those with an intact ventricular septum is dynamic subpulmonary stenosis reflecting the usually higher right ventricular pressure, often associated with abnormal systolic anterior motion of the mitral valve (Fig. 25C-3A,B).[21,22] Dynamic subpulmonary stenosis can be seen in the immediate newborn period, but becomes more obvious after the first few weeks of life with maturation of the pulmonary vascular bed and reduction of left ventricular pressure. Longstanding dynamic subpulmonary stenosis produces a fibrous ridge analogous to that observed in the patient with classic subaortic stenosis.[23–25] Thus in the evolution of a dynamic process, the dynamic subpulmonary obstruction may be complicated by fixed elements as well. Some years ago we reported our institution's experience with left ventricular outflow tract obstruction in 46 patients with complete transposition of the

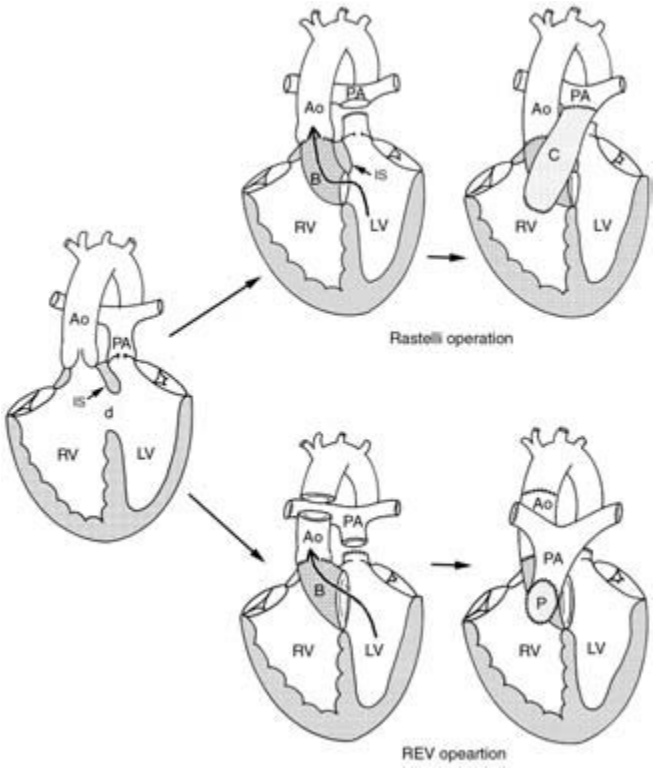

Fig. 25C-1 Rastelli and "réparation à l'etage ventriculaire" (REV) operations. Both procedures are for complete transposition of the great arteries, ventricular septal defect (d) and left ventricular outflow tract obstruction. In Rastelli operation, the left ventricle (LV) is tunneled to the aorta (Ao) by closing the ventricular septal defect (d) with a baffle (B). The pulmonary artery (PA) is divided, the proximal end closed and the distal end connected to a conduit (C) interposed between the right ventricle (RV) and distal main pulmonary artery. In REV operation, the infundibular septum (IS) is excised and the ventricular septal defect closed to the right of the aorta, and the pulmonary artery divided and oversewn proximally. A conduit is interposed between the right ventricle and pulmonary artery as in Rastelli operation, or alternatively, the distal pulmonary artery is mobilized sufficiently to allow a direct tissue connection with the ventricle, augmented anteriorly with a patch (P) as shown in the drawings. When the pulmonary artery cannot be pulled down to the right ventriculotomy site directly, the ascending aorta can be disconnected temporarily to mobilize the pulmonary artery anteriorly. In Rastelli operation, the tunnel of the left ventricular outflow tract makes acute turns (arrow in the middle diagram). In REV operation, the tunnel makes gentle curves (arrow in the middle diagram).

great arteries and essentially intact ventricular septum undergoing Mustard's operation.[24] The majority of these patients were found to have fibrous-fibromuscular obstruction, but about 20% were found to have abnormal mitral valve insertion; protrusion of the tricuspid valve through a restrictive ventricular septal defect into the left ventricular outflow tract; or other abnormalities of the atrioventricular valves (Fig. 25C-3). In only three patients was there a significant abnormality of the pulmonary valve requiring a commissurotomy, in two in isolation and in one, with associated fibromuscular left ventricular outflow tract obstruction. Chiu and colleagues have assessed those features of an intact ventricular septum susceptible to subpulmonary obstruction in transposition of the great arteries.[25] They found that in those patients with a bulging interventricular septum the aorta lay more anterior to the pulmonary trunk and these patients were more prone to develop a fibrous ridge on the left ventricular septal surface, consistent with left ven-

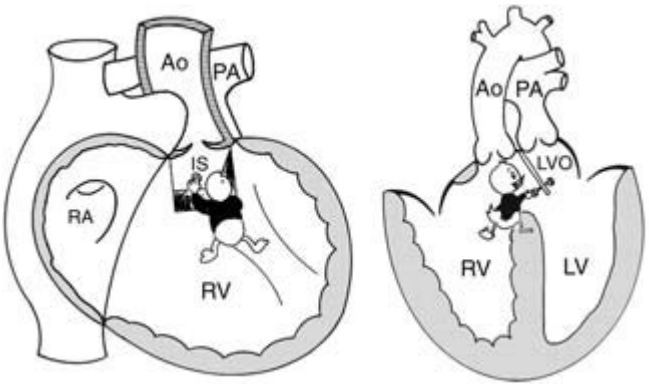

Fig. 25C-2 Mechanism of subpulmonary obstruction in association with posterior malalignment of the infundibular septum. The infundibular septum (IS, trap door) is pushed backward resulting in a posterior malalignment type of ventricular septal defect and narrowing of the subpulmonary outflow tract (LVO). Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

tricular outflow tract obstruction. Their morphologic findings also indicated that patients with transposition of the great arteries and a left anterior aorta were more likely to develop a septal bulge and left ventricular outflow tract obstruction. The so-called dynamic form of left ventricular outflow tract obstruction may become particularly severe and this may "prepare" the left ventricle for the arterial switch procedure when conducted past the first month of life when there is increased risk associated with this procedure.

In those patients with transposition of the great arteries and posterior displacement of the infundibular septum, the ventricular septal defect is frequently, but not invariably large.[14,16,17] The size and indeed position of the ventricular septal defect is strategic to biventricular and anatomic repair of transposition of the great arteries, ventricular septal defect and pulmonary outflow tract obstruction. The infundibular septum in these hearts both separates the arterial outlets and as well is a component of the interventricular septum. Malattachments of chordal apparatus, especially but not exclusively from the tricuspid valve, may "crowd" the ventricular septal defect and may make tunneling the left ventricle to the aorta difficult.[26,27] Such attachments may make resection of the infundibular septum hazardous as well.

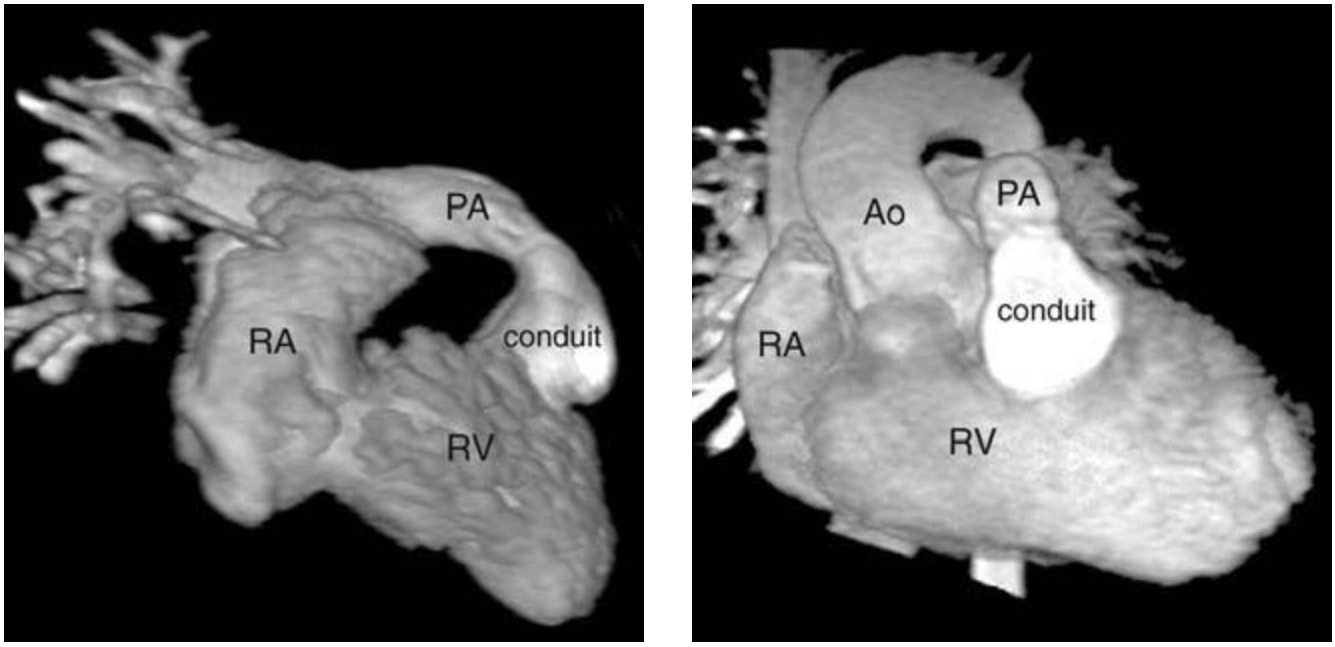
Patients with transposition of the great arteries, ventricular septal defect, and pulmonary stenosis share in common many anatomic features with patients with double outlet right (see Chapter 28) or left ventricle, or patients with so-called double discordance (see Chapter 26A). Because the assignment of specific ventriculoarterial connection may at times be difficult, some prefer to consider these hearts under the "umbrella" designation of hearts with abnormal ventriculoarterial connection, ventricular septal defect and pulmonary stenosis.[28–32] This overarching nomenclature is independent of the spatial relationship between the great arteries.[33,34] The basic goals and challenges of surgical intervention are the same for hearts with trans-position of the great arteries, ventricular septal defect, and pulmonary stenosis or double outlet right or left ventricle: connecting the morphologically left ventricle to the aorta without causing subaortic stenosis; completely separating the ventricles, and providing unobstructed continuity between the right ventricle and pulmonary arteries.[35] How these goals are accomplished and the outcomes of the innovative procedures are the topics of this chapter.

Outcome analysis

In a previous chapter (Chapter 25A) the fetal recognition of transposition and outcome of such pregnancies have been discussed. We have shown in an earlier study that about 4.1% of neonates with transposition who are potential candidates for the arterial switch operation die before operative intervention.[36] We cannot provide similar data for patients with complex transposition.

The patient with complex transposition of the great arteries, ventricular septal defect and left ventricular outflow tract obstruction has benefited from a variety of closed and open heart procedures. For many years these patients were palliated with some form of systemic-to-pulmonary artery shunt to augment pulmonary blood flow and later in childhood from a classic cavopulmonary shunt (see Chapter 35). Many required some form of atrial septectomy to enhance mixing at atrial level and this often took the form of a Blalock-Hanlon atrial septectomy. After 1966, when diagnosed as neonates, many underwent a Rashkind balloon septostomy (see Chapter 25A). The earliest attempts at repair began in the mid 1960s with the performance of a Mustard form of atrial repair, ventricular septal defect closure, and attempted resection and enlargement of the left ventricular outlet to the pulmonary artery.[2,37] The results of this approach were disappointing because the morphology of the left ventricular outflow tract did not lend itself to resection and remodeling.[2,37] This procedure was largely abandoned after the publication of Rastelli and his colleagues in 1969.[1–3] This innovative operation now bearing Rastelli's name tunneled the left ventricle through the ventricular septal defect to the aorta, closing the ventricular septal defect to the aorta (Figs 25C-1 lower panel, 25C-5). A conduit was interposed between the right ventricle and the distal pulmonary artery at the level of the confluence, with the main pulmonary trunk ligated or usually divided.[1–4] Because this procedure involved the use of a conduit, it was initially reserved for the older child.[1–4] In this regard the first patient repaired by Rastelli and his colleagues was a 14 $^1/_2$ year-old-boy who had been previously palliated with bilateral Blalock–Taussig shunts.[2] Sadly, as stated earlier, Gian Rastelli died so prematurely within a few years of this contribution from Hodgkin's disease.

The early results of the Rastelli procedure carried out at the Mayo Clinic were presented by Marcelletti and his colleagues in 1976.[38] Fifty-nine patients had corrective operation of the Rastelli type for transposition of the great arteries between 1968



A B

Fig. 25C-5 Rastelli operation. Contrast-enhanced MR angiograms (A and B) show the result of Rastelli operation. The conduit is mildly aneurysmal and there is mild stenosis in the distal conduit. Ao, aorta; LV left ventricle; PA, pulmonary artery; RV, right ventricle.

and 1975. In 12 patients (35%), the ventricular septal defect was enlarged by excising a portion of the septum. During the first 30 days after the operation, 11 patients (19%) died. The risk of repair in infancy in this era was greatly increased. There were 5 late deaths, and reoperation was required in 11 patients. Sixty-eight per cent of the survivors were in New York Heart Association (NYHA) class I and 29% were in class II. Some late complications related to deteriorations of the earlier aortic homograft conduit may be avoided by use of a Dacron conduit with a porcine valve, as suggested by short-term favorable results in 25 recent cases. The operative mortality decreased to 8% of the last 25 operations. These results led this group to conclude that the Rastelli operation is the procedure of choice for repair of transposition of the great arteries when associated with ventricular septal and pulmonary stenosis.[38]

Moulton and his colleagues also reported the early experience of the Great Ormond Street Hospital for Sick Children's experience with the Rastelli repair.[39] Forty-one children with transposition of the great arteries, ventricular septal defect, and left ventricular outflow tract obstruction underwent a Rastelli operation between 1971 and 1978. A variety of grafts from the right ventricle to pulmonary artery were used. The conduits were positioned to the left of the aorta whenever possible. The intraventricular tunnel from the left ventricle to the aorta was constructed from Dacron velour. There were 4 early and 7 late deaths. The last 13 consecutive patients all survived the operation. Early deaths were related to unfavourable anatomy, conduit compression, and sepsis. Residual ventricular septal defects and postoperative infection were the main factors contributing to the late deaths.

An important variation on the theme of Rastelli was published by LeCompte and his colleagues in 1982.[5,7] This operation was called "reparation a l'etage ventriculaire" or the REV procedure (Fig. 25C-1, lower panel). This operation departs from the classic Rastelli operation in that the infundibular septum is totally resected providing a short and direct tunnel from the left ventricle to the aorta, thus avoiding the potential for subaortic stenosis. The pulmonary artery is directly connected to the right ventricle without the use of a conduit.[5,7,40] Borromee, Lecompte and their colleagues provided in 1988 their early experience with the REV procedure in 50 patients who underwent anatomic repair of anomalies of ventriculoarterial connection associated with ventricular septal defect and pulmonary outflow tract obstruction.[32] The age at operation ranged from 4 months to 13 years (mean 3.5 years). Twenty-six patients had a classic type of transposition of the great arteries; all other patients had various types of anomalies of ventriculoarterial connection in which it was impossible, after the intraventricular connection of the left ventricle to the aorta, to use the natural pulmonary orifice for the pulmonary outflow tract reconstruction. There were 9 hospital deaths (18%) and 1 late death. Twenty-six of 29 patients whose follow-up time exceeded 1 year had an excellent clinical result. No stenosis of the aortic outflow tract was found. Four patients had significant pressure gradients in the pulmonary outflow tract.

Vouhe and his colleagues reported the outcomes of 62 patients who underwent complete repair for transposition of the great arteries, ventricular septal defect, and pulmonary outflow tract obstruction from 1980 to 1990.[41] Twenty-two patients (35%) (mean 8.1 ± 7.2 years) underwent the Rastelli operation: The ventricular septal defect was enlarged anteriorly in 8 patients, and right ventricular–pulmonary artery continuity was established with an extracardiac valved (9/22) or nonvalved (13/22) conduit. Forty patients (65%) (mean age 3.3 ± 3.2 years) underwent the Lecompte modifications. The infundibular septum was extensively excised when present (30/40), anterior translocation of the pulmonary bifurcation was performed in 32 patients, and right ventricular–pulmonary artery continuity was

established by direct anastomosis without a prosthetic conduit. There were 7 early deaths [11%; 70% confidence limits (CL), 7% to 17%]: 2 after the Rastelli procedure (9%; 70% CL, 3% to 20%) and five after the Lecompte operation (12.5%; 70% CL, 7% to 20%). Four patients were lost to follow-up, yielding a 93% complete follow-up (mean follow-up 55 months). There were 2 late deaths (1 in each group). Actuarial probability of survival (± SE) at 5 years was 83% ± 9% after the Rastelli operation and 84% ± 6% after the Lecompte procedure. All long-term survivors (except 1 in the Rastelli group) were in functional class I. Five patients in the Rastelli group underwent late reoperation for obstruction of the extracardiac conduit (28%; 70% CL, 16% to 42%). Three late reoperations (10%; 70% CL, 4% to 19%) were required after the Lecompte operation (1 for residual ventricular septal defect and 2 for residual pulmonary outflow tract obstruction). At most recent examination, residual pulmonary outflow tract obstruction was present in 7 patients of the Rastelli group (39%; 70% CL, 26% to 53%) and in 6 patients of the Lecompte group (19%; 70% CL, 12% to 29%). The combined likelihood of reoperation for pulmonary outflow tract obstruction and residual pulmonary outflow tract obstruction was significantly higher in the Rastelli group (67% vs. 26%; $P = 0.005$).

One of the issues that complicates intraventricular rerouting or tunneling the left ventricle to the aorta is attachment of tension apparatus from the tricuspid valve to the infundibular septum.[26] Some have considered this finding a contraindication to the Rastelli operation.[5,42,43] Niinami and his colleagues have addressed the management of so-called tricuspid malinsertion in the Rastelli operation by the use of the conal flap method.[44] In this method, the part of the infundibular septum bearing the tricuspid chordal attachments is mobilized by two incisions, one anterior and vertical and the other subaortic (Fig. 25C-6). This is then pulled backward as a pedicled flap. The intraventricular conduit is then sutured around the defect, thus simultaneously enlarging the ventricular septal defect.[44] In the study of Niinami, the outcomes of two groups of patients was assessed: both groups underwent a Rastelli operation, but one group with tricuspid chordal attachments to the infundibular septum underwent the conal flap method as well. There was virtually no difference in outcome, with minimal or no early mortality in each group. Postoperative echocardiograms revealed a slightly higher incidence of tricuspid regurgitation in the conal flap method when compared to the conventional group. Yet postoperative hemodynamic investigation showed similar right atrial mean pressures, right ventricular end diastolic pressure and volume (% of predicted normal) and right ventricular ejection fraction.[44] It is also of interest that during follow-up, the tricuspid regurgitation tended to improve, likely coincident with normalization of right ventricular pressures.[44] Another advantage of the conal flap method is that this procedure also enlarges the ventricular septal defect as in this series, 57% of the conventionally treated patients required enlargement of the ventricular septal defect.

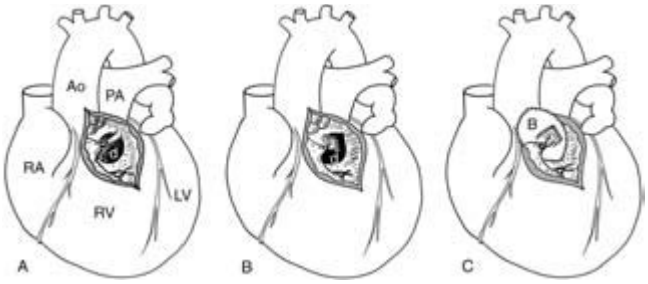


Fig. 25C-6 Niinami procedure. **A**. The interior of the right ventricular outflow tract showing tricuspid malinsertion to the infundibular septum across the ventricular septal defect (d). **B**. The part of the infundibular septum having chordal insertion of the tricuspid valve is mobilized and pulled backward as a pedicled flap. **C**. The intraventricular baffle (B) is then sutured around the defect and the pedicled flap is fixed to the baffle. Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

Kim and his colleagues reported the outcome of 19 patients treated by the Lecompte procedure for complete transposition of the great arteries associated with a ventricular septal defect and pulmonary stenosis operated on from December 1988 to February 1993.[45] The mean age at operation was 3.1 ± 0.8 years (mean ± SE). This technique consisted of resecting the outlet septum, constructing a tunnel that connected the left ventricle to the aorta, closing the proximal pulmonary arterial stump, pulling the distal pulmonary artery down to the right ventriculotomy site directly, and covering anteriorly with the fixed autologous pericardium. The early operative mortality was 5.3%. The mean follow-up was 24.2 ± 3 months, with no late death. One reoperation was performed because of residual right ventricular outflow tract obstruction. All survivors were studied by echocardiography at intervals of 6 months to 1 year. In all survivors (except for 1 child who underwent reoperation), the estimated pressure gradient between the right ventricle and the pulmonary artery, the structure of the left ventricular outflow tract, left ventricular function, and right ventricular contractility were all satisfactory.

Kim and his colleagues extended this series in 2001 by reporting the outcomes of 45 patients who underwent the Lecompte procedure during the past 11 years to achieve direct right ventricle to pulmonary artery continuity.[46] Mean age at operation was 2.4 ± 1.7 years (range 3.5 months to 6.9 years). The diagnoses involved anomalies of the ventriculoarterial connection with ventricular septal defect and pulmonary outflow tract obstruction, including transposition of the great arteries, double-outlet right ventricle, and double-outlet left ventricle. The early surgical mortality was 4.4% (2 of 45 patients) and late mortality was 4.7% (2 of 43). The mean follow-up was 4.9 ± 3.1 years. Fourteen patients (34.1% of survivors, $n = 41$) had pulmonary stenosis (pressure gradient > 30 mmHg), the main reason for which was a calcified monocusp valve ($n = 10$, 71.4%). Eight of 45 patients (17.8%) underwent reoperation: 2 for residual ventricular septal defect, 1 for recurrent septic vegetation, and 5 for pulmonary stenosis. The cumulative survival rates were 91.1% ± 4.2% at 10 years. The actuarial probabilities of freedom from reoperation for pulmonary stenosis were 93.8% ± 4.3% and 71.4% ± 11.8% at 5 and 10 years, respectively. The most important observation was that right ventricular outflow tract obstruction caused by degeneration of the monocusp valve was an ongoing problem.[46]

Pretre and his colleagues presented their retrospective analysis of 42 patients (median age at operation, 1.4 years) operated on between 1986 and 1999 for various forms of great artery malposition, ventricular septal defect, and pulmonary stenosis.[47] Relevant associated findings included the insertion of a tricuspid papillary muscle on the infundibular septum (nine patients),

absence of conal septum (6 patients), hypoplasia of a side pulmonary artery (4 patients), and hypoplasia of the right ventricle (1 patient). A preliminary systemic-to-pulmonary shunt was performed in 28 patients and a cavopulmonary anastomosis in 1 patient. At operation, the infundibular septum (whenever present) was resected (36 patients), the pulmonary bifurcation was usually translocated over the ascending aorta (37 patients), and the main pulmonary artery was enlarged with a patch of pericardium. A monocusp valve was fashioned within the patch in 40 patients. Follow-up information was complete in 32 patients and ranged from 0.4 to 14 years (mean, 5.4 ± 3.2 years). The survival rate at 5 years was 92 ± 5%. Three patients died postoperatively (mortality, 7%) but none thus far during follow-up. The freedom from reoperation was 86 ± 8 and 51 ± 22% at 5 and 10 years, respectively. Six patients were reoperated, all for pulmonary stenosis. Calcification of the monocusp patch was present in all. Pulmonary stenosis developed in three further patients: one underwent percutaneous dilatation and two are awaiting surgery (Fig. 25C-7).

In the past 2 years, comprehensive experiences with the Rastelli procedure have been published from the Mayo Clinic[48] and from the Children's Hospital in Boston.[49] Dearani and his colleagues from the Mayo Clinic reported on part of their 33-year experience with 231 patients operated on from June 26, 1968 to January 1, 2000.[48] This report focused on the late results of 160 early survivors who had been operated on from 1968 to 1990. The 160 patients ranged in age from 1 year to 44 years (median age at repair was 8 years, mean 9.7 years). One hundred and twenty-two patients had undergone 189 palliative operations. From 1968 to 1977, the mortality was 24.4% and this decreased to 4.8% from 1988 to 1997. Overall survival excluding early mortality was 82% at 5 years, 74% at 10 years, 69% at 15 years, and 59% at 20 years. The mean follow-up of the 160 hospital survivors was 11.9 ± 6.9 years. There were 53 late deaths of which 38 were considered cardiac in origin. Sudden death and arrhythmia accounted for 17 of these; congestive heart failure in 12; pulmonary hypertension in 5; endocarditis in 3, and myocardial infarction in 1. Freedom from reoperation for conduit failure was 78% at 5 years, 43% at 10 years, 29% at 15 years, and 27% at 20 years. Eighty-five patients required 107 conduit replacements. Sixty-six patients had one conduit replacement, 16 had two conduit replacements, and 3 patients required three conduit replacements. Subaortic stenosis was uncommon in this experience, with only 1% requiring reoperation. The mechanisms likely responsible for this complication are related to the size of the ventricular septal defect and failure of growth of the tunnel from the left ventricle to the aorta.[14,27,50,51] Others have reported the limited experience of the one-lung Rastelli operation.[49A,49B]

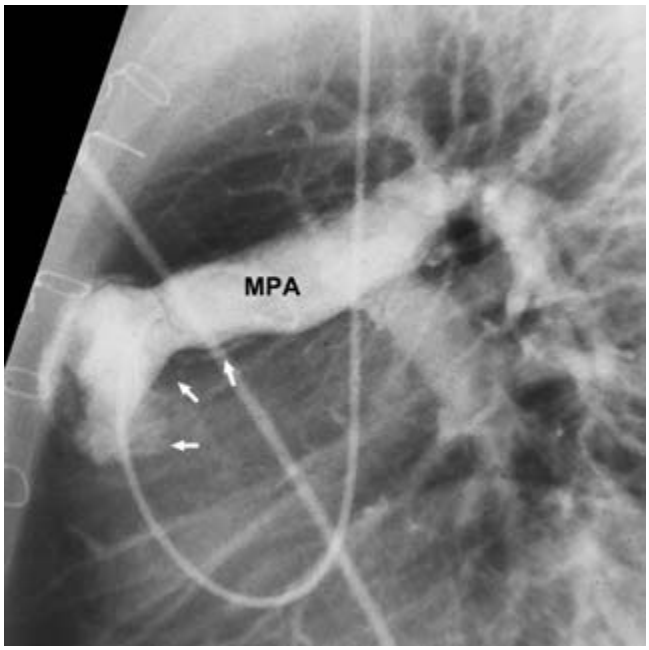

Fig. 25C-7 Pulmonary outflow tract obstruction after Rastelli operation. Conduit shows calcification and stenosis of its proximal part (arrows) and is fixed to the sternum.

Kreutzer and his colleagues from the Boston Children's Hospital presented in 2000 their review of 101 patients who underwent Rastelli's operation for complex transposition from March 1973 to April 1998.[49] Pulmonary stenosis was present in 73 patients and pulmonary atresia in 18; 10 patients had no left ventricular outflow tract obstruction. The median age and weight at the time of repair were 3.1 years and 12.8 kg, respectively. The majority of these patients had undergone some form of prior palliation, usually some form of systemic-to-pulmonary artery shunt and/or some form of atrial septectomy, either surgical or balloon-mediated. The ventricular septal defect was enlarged superoanteriorly in 47 patients, and only 2 patients had resection of the infundibular septum. A variety of conduit-types and procedures were used to provide continuity between the right ventricle and pulmonary artery. There were 7 early deaths which occurred in the early part of the experience, but no surgical deaths happened in the last 7 years of the study. When the deaths were stratified by age at repair, 3 of 24 patients < 1 year died; 4 of 69 patients aged 1–11 years died, and there were no deaths in the 8 patients ≥ 12 years. The causes of early death was related to residual left ventricular outflow tract obstruction in 3 patients, coronary insufficiency in 2, sudden atrioventricular block refractory to pacemaker therapy in 1, and pulmonary hypertension in 1. Survival at 1 month, 5 years, 10 years, 15 years, and 20 years was 93%, 82%, 80%, 68%, and 52%, respectively. At a median follow-up of 8.5 years (range 0.4–22.0 years) there were 17 late deaths and one heart transplant (Fig. 25C-8). The causes of late death were sudden death in 5, left ventricular dysfunction in 7, conduit pseudointima rupture in 1, myocarditis in 1, and 2 each, unknown or at reoperation. Freedom from death or reintervention (either surgical or catheter) was 53%, 24%, and 21% at 5, 10, and 15 years of follow-up, respectively. It is interesting to compare the need for reintervention on the left ventricular outflow tract in this paper compared to that from the Mayo Clinic.[48] Kreutzer and his colleagues found that 11 patients required surgical revision of the left ventricular outflow tract with no early deaths, considerably higher than the Mayo Clinic experience.[49] Reintervention, either surgical or catheter-based, on the right ventricular outflow tract was similar between the two groups. The Boston group reported freedom from reintervention for right-sided obstruction was 56%, 25%, and 21% at 5, 10, and 15 years, respectively.[49] Acknowledging a high incidence of postoperative complications, this group still advocates application of the Rastelli repair even to young infants, hoping to avoid the complications of and attrition from palliation.[49] The enlargement of the VSD in an anterosuperior direction by the

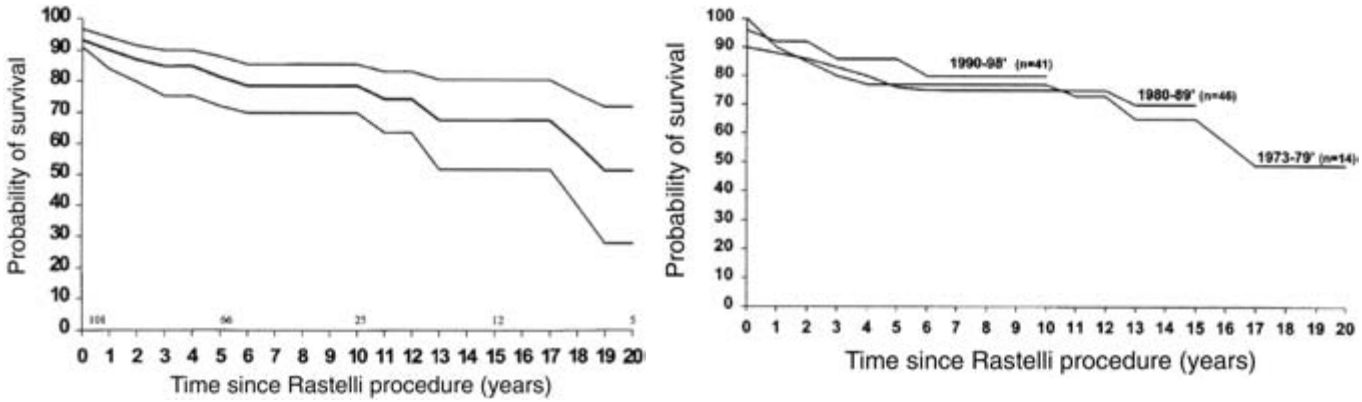

Fig. 25C-8 A. Overall survival of 101 patients at the Children's Hospital, Boston after the Rastelli operation, with 95% CL. B. Survival for three study periods. (Reprinted from Kreutzer *et al*.[49] Copyright (2000) Mosby Inc., with permission from Elsevier Inc.)

Boston group departs from the approach of Lecompte who enlarges the VSD by resecting the infundibular septum.[5–7] The Pediatric Cardiac Care Consortium has published its experience with the Rastelli operation.[52] This consortium identified between 1984 and 1994 1542 patients with transposition of the great arteries. The Rastelli operation was performed in 84 children ranging from 1.3 to 20.3 years with an average age of 7 years. The surgical mortality in this group was 8 of 84 (9.5%). No follow-up data were provided.[52] We have also reviewed our Rastelli experience which begins in 1974. Our total experience includes 80 patients, with thus far 10 early deaths (12.5%) and 13 late deaths (Figs 25C-9, 25C-10). Seventy-one patients had undergone prior palliation at a median age of 0.6 years. The median age at repair was 5.4 years, ranging from 0.2 to 36.8 years. The median follow-up is 9.4 years and 50% of the patients are now adults. The survival curve and freedom from reoperation for these patients are depicted in Figs 25C-9 and 25C-10. Thirty patients have required 43 reoperations at a median of 6.4 years after the initial operation. The majority of operations were necessitated by conduit change, with some late reoperations related to relieving subaortic stenosis. It is likely that the "REV" modification of Lecompte will reduce the requirement for reoperation/reintervention.[5,59]

Metras and Kreitmann have published a modification of the Rastelli-REV procedures.[53,54] Rather than a direct connection between the right ventricle and the pulmonary artery, they use an aortic autograft taken from the patient's ascending aorta to facilitate this connection. Sometimes a monocusp valve is positioned to provide temporary "pulmonary" valve competency. The authors favor this approach because the classic REV procedure with its direct connection between the right ventricle and the pulmonary artery places tension on the pulmonary connection, resulting in, as we have summarized, a frequent requirement for reintervention. The aortic autograft provides the potential for growth, and hopefully should obviate some of the need for reintervention. The drawback, of course, is the long-term effect of free pulmonary regurgitation on right ventricular function.

An interesting problem was reported by Deanfield and his colleagues.[55] A patient with transposition of the great arteries, ventricular septal defect, and obstruction of the left ventricular

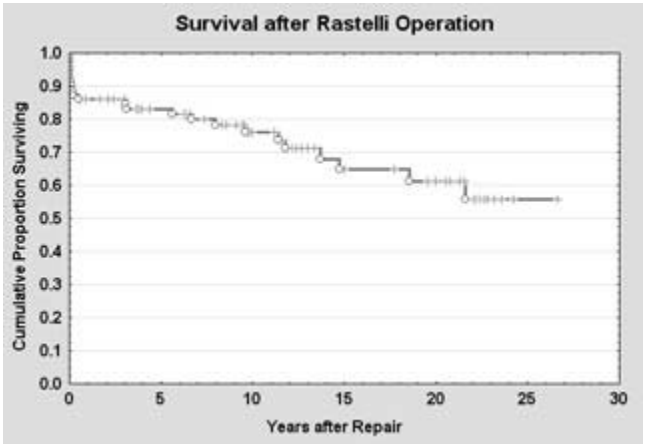

Fig. 25C-9 Kaplan–Meier actuarial survival curve of Rastelli patients from the Toronto Hospital for Sick Children and Toronto Hospital.

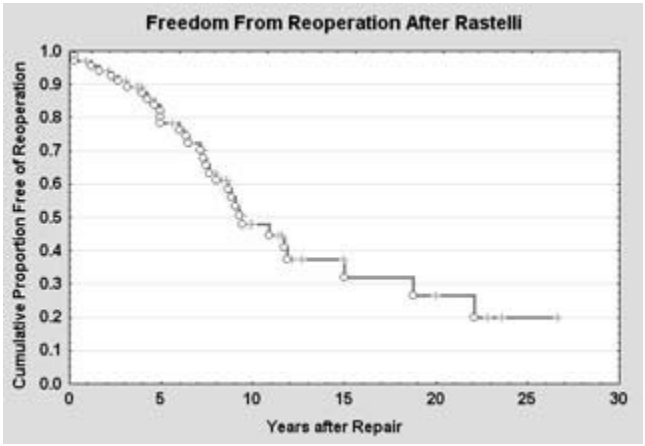

Fig. 25C-10 Kaplan–Meier actuarial survival curve depicting freedom from reoperation of Toronto patients.

outflow tract underwent a Rastelli repair. Unfortunately stenosis of the tricuspid valve was not recognised before or during operation; this severely compromised the postoperative hemodynamic function and necessitated reoperation. Insertion of a second homograft from the right atrium to the right ventricle bypassed the stenosis and resulted in a complete recovery with maintenance of a biventricular circulation. One would wonder in retrospect whether unloading the right ventricle with a bidirectional cavopulmonary shunt could have achieved the same result.

It should not be surprising that left ventricular failure has been observed in some patients after the Rastelli operation. Before the Rastelli operation, the patients usually are hypoxemic and the majority have been palliated with some form of systemic-to-pulmonary artery shunt that volume loads the left ventricle.[56,57] Graham and his colleagues have studied left ventricular wall stress in a small cohort of 11 patients after the Rastelli operation.[55] Left ventricular wall stress and contractile function were determined by echocardiographic methods in 11 patients.[55] They were studied 0.7–13.8 years (mean ± SEM = 5.6 ± 1.2 years) after undergoing the Rastelli operation for transposition of the great arteries associated with ventricular septal defect and left ventricular outflow tract obstruction. The age at operation ranged from 4.6 to 11.3 years (mean ± SEM = 7.4 ± 0.7 years). Data were compared with data of 24 normal subjects of similar age and heart rate. Left ventricular end-diastolic dimension and end-diastolic volume were significantly higher than normal, averaging 134% ± 8% of normal dimension ($P < 0.004$) and 106 ± 13 mL/m^2 vs. a normal volume of 60 ± 3 mL/m^2 ($P < 0.007$). In addition left ventricular wall mass was 215 ± 40 g/m^2 vs. a normal value of 72 + 6 g/m^2 ($P < 0.004$). Both meridional and circumferential end-systolic and peak systolic stress values were not significantly different between normal subjects and Rastelli patients. Estimates of ventricular pump function including shortening fraction, rate-corrected velocity of circumferential fiber shortening, and ejection fraction were all depressed when compared with normal values. Velocity of fiber shortening, evaluated as a function of end-systolic stress, demonstrated abnormal contractile function in eight of 11 (73%) patients. These data indicate that left ventricular function is usually abnormal and residual left ventricular dilation and wall hypertrophy remain despite successful application of the Rastelli operation.

Other applications of the Rastelli operation

The Rastelli operation has been combined with atrial repair of the Senning or Mustard types for the anatomical correction of atrioventricular discordance (see Chapter 26A).[58] Most patients who undergo this challenging operation have either double discordance or atrioventricular discordance with double outlet from the morphologically right ventricle.

In summary, both the Rastelli operation and the "REV" modification of Lecompte provide reasonable palliation for patients with transposition of the great arteries, ventricular septal defect and pulmonary stenosis as well as for other forms of hearts with abnormal ventriculoarterial connections. The long-term problems are likely related to:

- reintervention/conduit change
- pulmonary outflow tract obstruction and/or regurgitation (Fig. 25C-7)
- right ventricular dysfunction
- left ventricular dysfunction
- subaortic stenosis
- form and function of the atrioventricular valves
- cardiac rhythm disturbances
- sudden death.

Thus in the 35 years since the first Rastelli operations were carried out at the Mayo Clinic:

- This surgical technique conferred an anatomic repair for the patient with transposition of the great arteries, ventricular septal defect and pulmonary outflow tract obstruction.
- Early surgical mortality in recent years is < 5%. [48,49]
- Until recently, the patient with transposition of the great arteries, ventricular septal defect and pulmonary outflow tract obstruction has been repaired in stages: initial palliation and later repair.
- Repair frequently required the use of a right ventricle-to-pulmonary artery conduit, and thus the requirement for reoperation.
- There is now interest in primary repair even in infancy.[49]
- Early changes in ventricular geometry and ventricular septal defect size after the Rastelli operation contribute to the potential for late systemic outflow tract obstruction.[51] Thus some centers tend to routinely enlarge the ventricular septal defect.
- The introduction of the "REV" operation of Lecompte obviates the potential for subaortic stenosis and the translocation of the pulmonary artery to the right ventricle mitigates the requirement for right ventricle-to-pulmonary artery conduit. This operation with its resection of the infundibular septum also confers a geometrically shorter and more direct advantageous left ventricular outflow tract.
- The translocation of the pulmonary trunk to the right ventricle will lead to pulmonary regurgitation.

The late survival of the classic Rastelli operation is concerning.[48,49] Whether earlier repair will have an advantageous effect on late outcome is to be determined. It is unclear at this time whether the classic Rastelli or "REV" operation of Lecompte is or should be the operation of choice.[59] If the VSD is now routinely enlarged in the Rastelli operation,[49] then one must weigh the effects of conduit replacement vs. chronic pulmonary insufficiency on the long-term outcomes of these patients. Finally, Yamagishi and colleagues have reported in one patient an innovative approach to repair of complete transposition of the great arteries, ventricular septal defect and pulmonary stenosis.[60] This so-called half-turned truncal switch operation has the potential advantage of ensuring straight and nonobstructive aortic and pulmonary ventricular outflow tracts by using a half-turned truncal block that includes both semilunar valves. Only time will tell whether this approach gains greater popularity.

Conditions with Double Discordance (Congenitally Corrected Transposition of the Great Arteries)

It has been more than 115 years since Von Rokitansky first described two cases in which transposition of the great arteries was functionally corrected by the position of the interventricular septum.[1] Monckeberg and later Uher described the anterior atrioventricular node, a very important finding for surgical intervention in this condition.[2,3] That more than 60 years ago hearts exhibiting congenitally corrected transposition were considered novel is illustrated by the review of Harris and Farber, who in their compilation of 1939 could collect only 17 cases, whereas Anderson and Schiebler and their colleagues were able to increase the number to somewhat more than 100.[4–6] Data from the Hospital for Sick Children in Toronto published by Bjarke and Kidd in 1976 summarized more than 100 patients, and the institution's database has now been extended even further.[7]

Congenitally corrected transposition of the great arteries is an uncommon congenital cardiac anomaly characterized by double discordance: a discordant atrioventricular and ventriculoarterial connection (Fig. 26A-1).[8–11] While double discordance occurs in isolation, far more commonly the situation is complicated by associated ventricular septal defect, pulmonary outflow tract obstruction, and anatomic disturbances causing regurgitation of the systemic, morphologically tricuspid valve.[8–26] Furthermore because of the unusual disposition of the specialized conduction tissue, these patients are prone to congenital and acquired complete heart block.[27–31] And, it is the systemic morphologically right ventricle that supports the systemic circulation. As Richard van Praagh said more than two decades ago and Warnes more recently, one should hardly consider this condition "corrected!" [32,33]

Incidence and extracardiac malformations

Using data from the Hospital for Sick Children in Toronto, Bjarke and Kidd identified amongst 10 535 patients with congenital heart disease, 101 with corrected transposition of the great arteries, thus giving a prevalence of 0.95%, but these data included patients with a univentricular atrioventricular connection.[7,34] Excluding these patients would reduce the prevalence to 0.57%, similar to the 0.43% found by Beuren.[35] The New England Regional Infant Cardiac Program identified only 16 infants with corrected transposition of the great arteries.[36] This number provided a prevalence of 0.02/1000 live births. The Baltimore–Washington Infant Study identified 47 patients with corrected transposition of the great arteries from 4390 infants surveyed from 1981 to 1989.[37] Data recently provided by Fyler addressing patients seen at the Boston Children's Hospital revealed that over a 15-year period to 1987, 89 patients with corrected transposition of the great arteries were seen, or 0.6% of those with congenital heart disease.[38] The recently completed prospective Bohemia Survival Study identified 22 children born with double discordance among 815 569 children born between 1980 and 1990.[39] This provided a prevalence of 0.03 per 1000 live births, and these accounted for 0.4% of all congenital heart malformations encountered in this study.[39]

Morphological considerations

The heart position and its apex may be normal (levocardia), in the midline (mesocardia), but in about 20% of patients with congenitally corrected transposition of the great arteries, the cardiac apex is predominately right-sided, that is, dextrocardia. The atrial situs is solitus in *c*. 92–95% of patients; an inverse atrial situs was recorded in 5–8%. Some patients with congenitally corrected transposition of the great arteries will have a so-called twisted atrioventricular connection. Most of the morphological considerations germane to the patient with double discordance are relevant to the patient with atrioventricular discordance no matter what the ventriculoarterial connection: double-outlet ventricle; concordant ventriculoarterial connection; single outlet; or common arterial trunk.

While the ventricles in hearts with corrected transposition of the great arteries may be considered inverted, they are not in a mirror-image of a normal heart.[9–12] As pointed out by Losekoot and his colleagues, this is in large part a consequence of the fact that the arterial outflows are parallel to each other (Fig. 26A-1), remembering that in the normal heart the outflow tracts cross.[9–11] The internal organization of the morphologically right ventricle in hearts with solitus atria conforms to a left-hand pattern of internal organization. Rarely the pattern of internal ventricular organization will be non-harmonious with the type of atrioventricular connection.[40–46] Usually the aorta is anterior and to the left of the pulmonary trunk in the classic expression of congenitally corrected transposition of the great arteries, but this spatial relationship is not pathognomonic for this condition.[47–49]

The coronary arteries originate from the posterior facing sinuses of the aortic valve.[10–13,16–19,50–53] In patients with atrial situs solitus and congenitally corrected transposition of the great arteries, the coronary arteries show a mirror-image distribution. The right-sided coronary artery has the epicardial distribution of a morphologically left coronary artery, with the main right-sided coronary artery bifurcating into circumflex and anterior descending branches, while the left-sided coronary

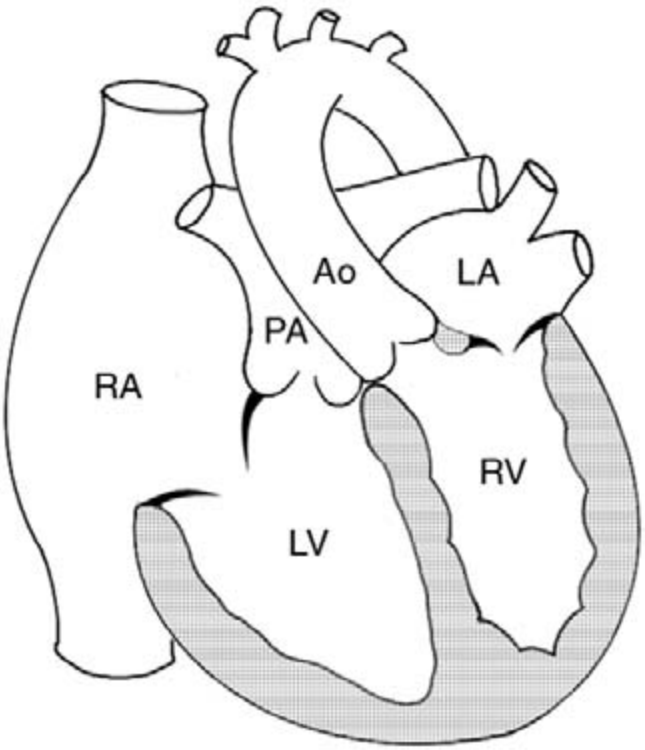

Fig. 26A-1 Illustration showing congenitally corrected transposition of the great arteries. Both atrioventricular and ventriculoarterial connections are discordant. Ao, aorta; LA, left atrium; LV left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

artery runs in the left atrioventricular groove, and gives rise to infundibular and right ventricular branches.[10–13,16–19,50–53]

The most commonly associated anomalies in patients with atrioventricular discordance include: (1) ventricular septal defect; (2) pulmonary outflow tract obstruction; (3) dysplasia and displacement of the left or systemic atrioventricular valve; (4) combinations of these associated lesions.[5–16,18–33]

Ventricular septal defect

A ventricular septal defect is the most common associated malformation in congenitally corrected transposition of the great arteries, having an incidence in clinical material of between 60% and 70%, and nearly 80% in autopsy material (Fig. 26A-2).[11] The most common ventricular septal defect is perimembranous and tends to be large. The ventricular septal defect is usually large, reflecting the malalignment between the atrial septum and ventricular septum characteristic of hearts exhibiting atrioventricular discordance, and the resulting left-to-right shunt important. The ventricular septal defect may be subarterial and roofed by the semilunar valves. This is uncommon in the Occidental, but not uncommon in the Oriental.[23] The ventricular septal defect can occupy any position.

Pulmonary outflow tract obstruction

Obstruction to the outflow tract of the morphologically left ventricle is identified in from 30–50% of patients with corrected transposition of the great arteries and atrial situs solitus (Fig. 26A-3).[8–21] Pulmonary outflow tract obstruction uncommonly occurs in isolation at valve or infundibular level but is more typically associated with a large ventricular septal defect (Fig. 26A-2). In about one-third of these patients with ventricular septal defect and pulmonary outflow tract obstruction, abnormalities of the morphologically tricuspid valve are seen as well. The left ventricular outflow tract obstruction is usually muscular, reflecting wedging of the subpulmonary outflow tract between the infundibular septum and the ventricular free-wall, with contributions from the right-sided ventriculoinfundibular fold as well. Fibrous tissue derived from the membranous septum may contribute to left ventricular outflow tract obstruction, and this may be wholly resectable (Fig. 26A-4). Tissue tags derived from tricuspid or mitral valve or from the pulmonary valve itself may obstruct flow into the pulmonary trunk. Blood cysts may also participate in subpulmonary obstruction. Single-outlet aorta with pulmonary atresia is well recognized with atrioventricular discordance.

The systemic, morphologically tricuspid valve

Abnormalities of the morphologically tricuspid valve are intrinsic to hearts exhibiting atrioventricular discordance.[5–22,25,26,50] While at the autopsy table, about 90% of hearts exhibit some abnormality of the morphologically tricuspid valve, considerably fewer demonstrate a functional disturbance during life. The most common and important underlying pathology is dysplasia of the valve, with or without displacement of the septal or posterior leaflets of the tricuspid valve (Fig. 26A-5).[25] Some hearts with congenitally corrected transposition of the great arteries will exhibit an unguarded tricuspid orifice, most with aortic

atresia as well, while in others the tricuspid valve may straddle and override a muscular inlet ventricular septal defect.[54–60] A stenotic, Ebstein-like tricuspid valve dividing the morphologically right ventricle has also been described.[61]

Other associated anomalies include a straddling and/or overriding left atrioventricular valve; superoinferior ventricles; coarctation of the aorta; interruption of the aortic arch; aortic or subaortic stenosis; hypoplasia of one ventricle (usually in association with a disturbed atrioventricular valve ipsilateral to the hypoplastic ventricle), and common arterial trunk. Functional or anatomic aortic atresia has been found in some patients with congenitally corrected transposition of the great arteries, and all such patients have had massive regurgitation of the systemic atrioventricular valve with a terribly disordered morphologically right ventricle, with marked thinning of its myocardium.[54–60] The systemic atrioventricular valve is very abnormal in these patients exhibiting features of dysplasia, displacement; and in some of the newborns the tricuspid annulus may be virtually unguarded. The systemic atrioventricular valve is more commonly abnormal than the morphologically mitral valve. Straddling of the mitral valve has been noted in patients with corrected transposition of the great arteries.[62] Clearly functional disturbances of the mitral valve are far less common than similar disturbances of the tricuspid valve. Yet in an autopsy study of 29 specimens of hearts with congenitally corrected transposition of the great arteries, 16 (55%) demonstrated abnormalities of the mitral valve.[62,63] The most common of these

included abnormalities in cusp number and tension apparatus (each 21%), while less common findings included dysplasia, common atrioventricular orifice, stenosis, and cleft valve. In a rare case the mitral valve may be unguarded.[62A] Isolated aortic stenosis has also been observed in the patient with congenitally corrected transposition of the great arteries. Even in the adult with congenitally corrected transposition of the great arteries, patients will develop progressive systemic atrioventricular valve regurgitation unrelated to operation.

The specialized conduction tissue

Intrinsic to hearts exhibiting atrioventricular discordance is a particularly fragile specialized conduction system. It is the

unusual disposition of the conduction tissue that predisposes patients with atrioventricular discordance to spontaneous heart block. The sinus node is normally positioned in these hearts, but the atrioventricular conduction tissue is grossly abnormal. The abnormal disposition has been elegantly reviewed by Losekoot, Anderson, and others.[27–30] In brief, the basic anatomy dictates that the regular atrioventricular node, located at the apex of the triangle of Koch, cannot give origin to a penetrating atrioventricular conduction bundle. Thus an anomalous second atrioventricular node is present, located beneath the opening of the right atrial appendage at the lateral margin of the area between pulmonary valve and mitral valve continuity. As pointed out by Losekoot and Becker this anteriorly positioned node gives rise to the atrioventricular bundle which comes to lie immediately underneath the pulmonary valve leaflets.[11] The non-branching bundle has a superficial course underneath the right anterior facing leaflet of the pulmonary valve and descends for some distance before it branches. We have experienced the onset of complete heart block in the catheter laboratory before catheter manipulation.

Less common associations

Most series dealing with outcome of patients with atrioventricular discordance include those "close cousins" with other forms of ventriculoarterial arrangements. Atrioventricular discordance can occur with double-outlet of both great arteries from the morphologically right ventricle; double-outlet left ventricle; single-outlet aorta with pulmonary atresia or with normal ventriculoarterial connections. This latter condition has also been designated as isolated ventricular inversion or isolated atrioventricular discordance (see Chapter 26B). Other relatively uncommon conditions include a supravalvular stenosing ring of the left atrium; subaortic stenosis; and left ventricular hypoplasia with or without pulmonary atresia and intact ventricular septum; and hypoplasia of either the morphologically right or left ventricle.[12]

Outcome analysis

The long-term outcome of patients with double discordance is closely associated with the complexity of the associated anomalies, the form and function of the morphologically right ventricle and the competency of the morphologically tricuspid valve. A further issue for these patients is the potential for complete heart block. There is only scant information on the outcome of fetuses recognized to have double discordance. Allan states that the prognosis for the affected fetus tends to be poor because fetal detection is often predicated on the recognition of the associated malformations.[64] In her series, of the 19 cases diagnosed prenatally, the pregnancy was terminated in 7; there were 2 neonatal deaths and 8 were alive, most with clinically significant systemic atrioventricular valve regurgitation.[64]

Before 1987 and the report from Ilbawi and his colleagues,[65] patients with double discordance and associated conditions were treated with a variety of standard open and closed heart procedures. Early in the surgical history of this condition, those with a large ventricular septal defect underwent banding of the pulmonary trunk followed at a later date by debanding and patch closure of the ventricular septal defect.[12,13,16] Some by the late 1970s preferred one-stage repair of the ventricular septal defect.[16,20,22,23] Repair of the ventricular septal defect was frequently complicated by complete heart block until de Leval introduced the concept of ventricular septal defect closure from the morphologically right ventricular septal side.[30] Those with double discordance, ventricular septal defect and important pulmonary outflow tract obstruction would often be palliated in infancy with a systemic-to-pulmonary artery shunt, and later repair.[16,20,66–67] The repair included patch closure of the ventricular septal defect with a conduit interposed between the morphologically left ventricle and the pulmonary trunk.[16,20,66,67] The tricuspid valve would be repaired or replaced, but in the classic repairs just described, the tricuspid valve would be left in the systemic circulation. Those with important ventricular hypoplasia could be considered for single ventricle palliation, while those with concordant ventriculoarterial connections and two well-formed ventricles can be treated with an atrial inversion-type of repair (see Chapter 26B).

Data recently published on the Prospective Bohemia Survival Study indicated that of 22 children identified at birth with double discordance, 94.45% survived the first month.[39] An additional decline occurred between the first and sixth months of life to 82.27%, and at 3 years to 72.73% and remained at this level to the age of 15 years. Huhta and his colleagues reviewed the natural history of 107 patients with congenitally corrected transposition of the great arteries seen at the Mayo Clinic over a 30-year period (1951–81).[68] The only variable correlating with decreased survival was left atrioventricular valve insufficiency. These authors reported survival of 70% at 5 years and 64% at 10 years. Clearly this is a "biased" series because of the unique referral pattern of the Mayo Clinic. The mean age at Mayo Clinic diagnosis was 12.7 years, ranging from birth to 56 years.

Data on the natural history of the patient with congenitally corrected transposition of the great arteries have been provided by Lundstrom and colleagues from the United Kingdom.[69] They reviewed data on 111 patients with a biventricular heart managed over a 20-year period to 1988. The ages of survivors in their cohort ranged from 1 to 58 years, with a median of 20 years, and all but 10 had additional cardiac difficulties. Twenty-six patients had died by 1988. Sixteen patients were considered unlikely to require surgery because of absent or trivial associated cardiac lesions. Because of considerable heterogeneity in associated cardiac lesions, it became evident that patients who were very symptomatic from heart failure did not fare well. In addition, those young patients with severe tricuspid regurgitation and/or a failing morphologic right ventricle also did poorly. Data from Boston Children's Hospital suggest a more favorable outcome, but the data do not include as long a follow-up.[38] McGrath and colleagues have addressed death and other events after cardiac repair in 99 patients with discordant atrioventricular connections.[70] The 1-month, 1-year, and 10-year actuarial survival rates of these 99 surgical patients were 86%, 75%, and 68%, respectively. Voskuil and colleagues have also studied the post-surgical course of 73 Dutch patients from three institutions with double discordance.[71] Not surprisingly they found survival of patients with double discordance was significantly below normal, and in most patients right ventricular and tricuspid valve function deteriorated with age. Both of these complications developed more frequently after conventional intracardiac operations compared with patients undergoing palliative intervention or no surgery at all.

Prieto and her colleagues have studied systemic atrioventricular valve function in 40 patients with double discordance. Follow-up in these patients ranged from 7 to 36 years, with a

mean of 20 years.[72] Intracardiac repair was carried out in 21 patients and 19 were unoperated upon or had closed heart procedures. The only independently significant factor for death in their analysis was moderate to severe tricuspid regurgitation. For the entire cohort, 20-year survival without tricuspid regurgitation was 93%, but only 49% with tricuspid regurgitation. Twenty-year survival rates for operated patients with and without tricuspid regurgitation were 34% and 90%, respectively. Similarly, 20-year survival rates for unoperated patients with and without tricuspid regurgitation were 60% and 100%, respectively. This group concludes that tricuspid regurgitation represents the major risk for patients with double discordance, and that right ventricular dysfunction appeared to be a consequence of chronic tricuspid regurgitation. Many other studies are in agreement that right ventricular dysfunction and tricuspid regurgitation deteriorated more frequently following intracardiac operation than those either unoperated or treated with closed heart procedures.[66,67] In view of these observations on the importance of satisfactory tricuspid valve function in the outcome of these patients, we are challenged by Acar and associates to maintain tricuspid valve competence in double discordance.[73] As summarized by this group tricuspid valve function in double discordance with an abnormal tricuspid valve depends on the loading conditions of both ventricles and on the septal geometry.[73] Interventions that increase right ventricular volume or decrease left ventricular pressure induce and worsen tricuspid regurgitation. Furthermore in their experience, repair of the tricuspid valve always failed when the right ventricle was left in a systemic position and always succeeded when the right ventricle was incorporated into the pulmonary circulation.[73]

The unique disposition of the specialized conduction tissue sets the stage for the development of spontaneous heart block in any cohort of patients with congenitally corrected transposition of the great arteries. About 10% of patients may actually present in complete heart block. Data presented by Fyler based on the Boston Children's Hospital experience indicates that in a 20-year follow-up, 45% of the patients will have developed third-degree heart block.[38] This figure is somewhat higher than the figure of 30% suggested by Mullins.[13] Because acquired heart block frequently occurs in the setting of associated cardiac anomalies, the bradycardia is not well tolerated, and urgent pacemaker therapy is mandated. It has been suggested that spontaneous complete heart block in this population occurs at a rate of about 2% per year.[16,68–70]

One of the conundrums of this disorder is the question: Can the morphologic right ventricle function as the systemic right ventricle in the long term? This question has been addressed in several ways. First, some argue that the shape of the morphologically right ventricle; the configuration of the tricuspid valve; the disposition of the papillary muscles of the tricuspid valve; the fact that the right ventricle is a one-coronary artery ventricle whereas the left ventricle is a two-coronary artery ventricle, all these factors disadvantage the morphologically right ventricle as a systemic ventricle.[10] In addition, there are a number of reports of adults in the sixth, seventh, eighth, and ninth decades of life with congenitally corrected transposition of the great arteries who have come to medical attention for either cardiac or noncardiac reasons.[74–86] Such patients are used as evidence that, indeed, the right ventricle can function as the systemic right ventricle for many years. Benson and his colleagues and others provided evidence, based on radionuclide assessment of ventricular function, supporting preservation of right integrity.[87,87A,87B,87C] A similar conclusion based on different methodology was reached by Dimas and colleagues.[77] Yet data from Peterson *et al.*[88] suggest that the systemic ventricular ejection fraction does not increase from rest to exercise, indicative of an abnormal exercise response. The issue has not been completely resolved, although at rest systolic function of the systemic morphologic right ventricle may be reasonably well preserved. Relatively few data on morphologic right ventricular diastolic function are available. From clinical experience it is evident that patients with a systemic ventricle of right ventricular morphology are at some risk of contractile dysfunction. Hornung and colleagues have provided some evidence using sestamibi scanning that in patients with double discordance but without any additional associated cardiac anomalies have a high prevalence of reversible and fixed myocardial ischemia, and these defects were mostly associated with impaired wall motion and thickening.[89] In the patients studied the younger patient had a normal right ventricular ejection fraction, while it was somewhat reduced in the older patients. Dodge-Khatami and colleagues have compared systemic ventricular (morphologically left ventricle) function in healthy adult controls and patients with unoperated double discordance using MRI dobutamine stress testing.[89A] They found that compared with the left ventricle of the healthy controls, the systemic ventricles of patients with unoperated double discordance and patients with physiologically corrected double discordance had larger volumes, diminished ejection fraction, but an appropriate response to dobutamine stress. They also found that the values of unoperated patients with double discordance were closer to normal than those with double discordance who had undergone physiological repair.

But as one surveys the outcome of any substantial cohort of patients with double discordance, some will develop progressive systemic atrioventricular valve regurgitation after otherwise apparently successful surgery.[10,12,13,16,20,33,65,66,67,68–73] Others will demonstrate progressive deterioration in the form and function of the morphologically right ventricle, the systemic ventricle, a concern well known to the survivor of the Mustard or Senning repair for complete transposition of the great arteries (see Chapter 25A). In others progressive tricuspid valve incompetence and a failing systemic right ventricle will beg the question as to what is the main culprit: the failing ventricle leading to progressive tricuspid regurgitation, or progressive tricuspid regurgitation causing right ventricular failure, again a similar concern for the survivors of atrial repair for transposition. Indeed, these concerns about the outcome of the atrial switch patients stimulated the interest in the arterial switch protocol, a goal finally achieved by Adib Jatene of Sao Paulo, Brazil, in 1974, after the disappointing results of Mustard two decades earlier (see Chapter 25B). It was Ilbawi and his colleagues in the late 1980s who first reported a surgical maneuver that would allow the morphologically left ventricle to function as the systemic ventricle in the patient with double discordance.[65] In two patients with complex double discordance, ventricular septal defect, and pulmonary outflow tract stenosis/atresia, a venous switch operation was combined with a Rastelli-like operation in which the ventricular septal defect was tunneled to the left ventricle and aorta, and a conduit was interposed between the morphologically right ventricle and pulmonary artery. This allows the morphologically left ventricle to function as the systemic ventricle and places the morphologically right ventricle in the pulmonary circulation. By reducing the afterload on the morphologically

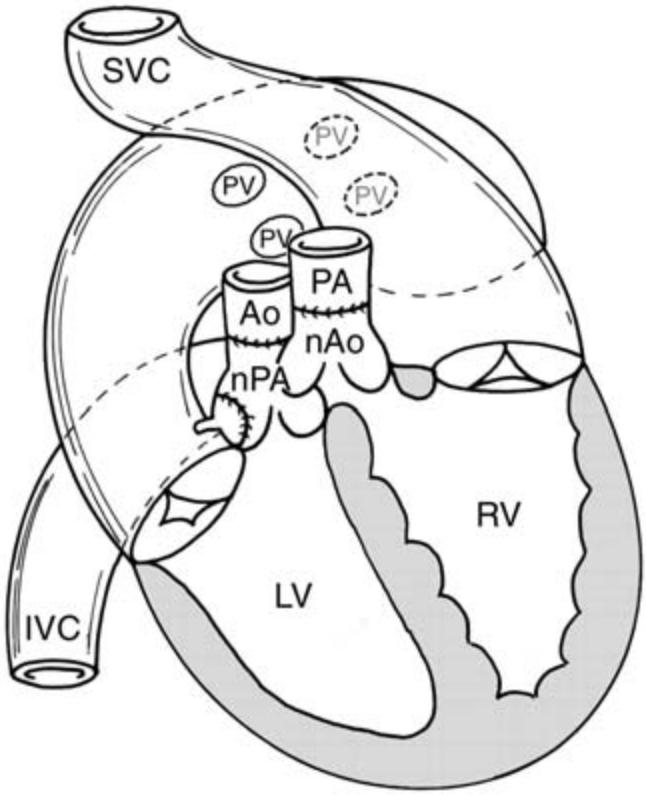

Fig. 26A-6 Double-switch operation of Imai *et al.* Mustard or Senning procedure is performed at the atrial level to divert the systemic venous flow to the morphologically right ventricle (RV) on the left side and the pulmonary venous flow to the morphologically left ventricle (LV) on the right side. Then, the arterial switch procedure is performed to establish concordant ventriculoarterial connection. Ao, aorta; IVC, inferior vena cava; nAo, native aorta; nPA, native pulmonary artery; PA, pulmonary artery; PV, pulmonary vein; SVC, superior vena cava.

right ventricle, this should improve the function of the tricuspid valve. Within a few years after the report from Ilbawi and his colleagues emanated the report of Imai and his colleagues of a combined atrial and arterial switch: a true double-switch for double discordance (Fig. 26A-6).[90] There is now a considerable surgical experience with the double-switch operation, both atrial switch and Rastelli and the true double-switch.[91–108] The theoretical benefits of these operations are apparent, but both forms of double-switch are accompanied by their own potential problems. Both types involve an atrial switch operation, and the mechanical and electrical complications of the atrial switch operation (Mustard or Senning) have been dealt with elsewhere (see Chapter 25A). The Rastelli approach frequently requires enlargement of the VSD and this is not without potential hazards to the patient.[106] This is not unusual considering the observations of Rychik and his colleagues.[106A] In the pure double switch, there are the long-term complications associated with coronary artery transfer, etc. None the less, the double-switch protocol has been quickly assimilated into our surgical algorithms, and there are clinical data suggesting excellent long-term outcomes from this approach.[96A,109,109A,109B]

Yeh and his colleagues from the Toronto Hospital for Sick Children have reported the outcome of repair in 127 patients with atrioventricular discordance from 1959 to 1997, extending the observations from our earlier experiences with this condition.[110] The ventriculoarterial connection was discordant in 87%, concordant in 6%, double-outlet right in 6%, and double-outlet left in 1%. At the initial presentation, the most common lesions in these 127 patients were ventricular septal defect in 86%, pulmonary outflow tract obstruction in 64%, important tricuspid regurgitation in 28%, and atrioventricular block in 12%. Nine patients underwent a double switch procedure and the remainder were managed conventionally. The operative mortality was 6% and did not vary by associated lesion. Twenty years after repair survival was only 48%. Within 20 years, 56% required reoperation, usually for tricuspid valve incompetence, pulmonary outflow tract obstruction, or both (Fig. 26A-7). Pacemakers were required in 50 patients, 4 before repair, 40 within 2 months of repair, and 6 remotely after repair. Tricuspid valve failure was an important cause of morbidity and mortality, both at initial repair and during subsequent follow-up. Forty-two of the 127 patients (34%) have required tricuspid valve repair or replacement to date. Twenty-seven of these required tricuspid valve replacement or repair at the initial operation. Of these 27, 4 have required a subsequent operation for tricuspid valve failure at a mean age of 10 years (median 14.2 years) after the initial repair. Of the 98 patients who did not require tricuspid valve surgery at the initial repair, 14 (14%) required subsequent tricuspid valve surgery by a mean age of 19.9 years (median 17.4 years). Fifty per cent of our patients with atrioventricular discordance required tricuspid valve surgery by 35 years of age, and tricuspid valve failure requiring surgery increased with age. Pulmonary conduit failure was also an important source of morbidity and mortality. Of the 66 patients who had a pulmonary conduit placed at the initial repair, within 12 years, 49% required conduit replacement. Twenty years after the initial

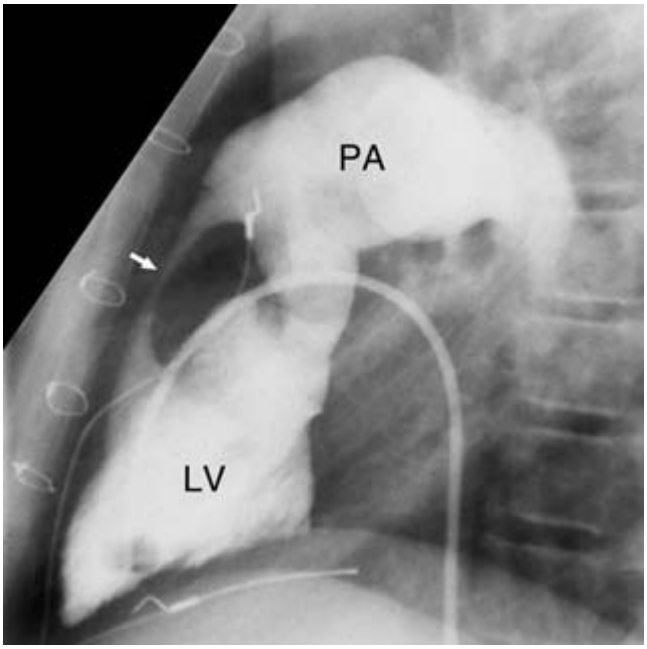

Fig 26A-7 Important stenosis (arrow) of the right ventricle-to-pulmonary artery homograft conduit in a patient with congenitally corrected transposition and severe left ventricular outflow tract obstruction. LV, left ventricle; PA, pulmonary artery.

repair, 60% of the patients were free of pacemaker placement. In our early experience with the double-switch protocol, mortality was equivalent, but half the patients required a pacemaker for atrioventricular block, usually associated with the need to enlarge the ventricular septal defect. The overall survival from birth of our entire cohort of patients with double discordance is shown in Fig. 26A-8.

Graham and his colleagues in a multi-institutional study have addressed the long-term outcome of 182 adult patients 18 years of age or older from 19 institutions.[111] Two groups of patients were compared: group 1 with associated conditions and group 2, no associated lesions. No difference in ages was seen between the two groups, and for the entire 182 patients averaged 32 ± 13 years (range, 18–75 years). Clinical findings of congestive heart failure was common in both groups, but more common in those with associated lesions (51% vs. 34%). By age 45 years, 67% of patients in group 1 had congestive heart failure compared to only 25% of patients in group 2. Systemic right ventricular dysfunction was common in both groups, 70% and 55%, as was tricuspid regurgitation, 82% and 84%. Dysfunction of the morphologically left ventricle supporting the pulmonary circulation was identified in 25% of patients in group 1 and in only 7% in group 2. Aortic regurgitation was similar in both groups, 36% in group 1 and 25% in group 2. For clinical congestive heart failure and right ventricular dysfunction, the strongest risk factors included tricuspid valve surgery, important tricuspid regurgitation, history of any open heart surgery, and pacemaker therapy. Similar findings have been reported by Connelly and his colleagues from the Toronto Congenital Cardiac Center for Adults.[80]

How and why new operations are introduced is the subject of some interest.[109] This has been discussed in the context of the rapid evolution from the atrial switch to the arterial switch for complete transposition of the great vessels. Indeed, the answer today to the question "Why switch?" is obvious and the midterm results certainly justify the change in surgical protocol.[112] But is the change in protocols for double discordance justified, a reasonable question posed from colleagues at the Mayo Clinic.[113] They caution us that while the operative results and early follow-up have been optimistic, to this date no intermediate or long-term results have been published. To this end, the Mayo Clinic group offers their results and follow-up data for comparison. They reported in 2001 on 111 children operated on from July 1, 1971 to January 31, 1996. Complex associated anomalies included double-outlet right ventricle in 43 and situs abnormalities in 38. Patch or suture closure of a ventricular septal defect was required in 101 patients, a conduit from the morphologically left ventricle to the pulmonary artery in 65 patients, repair or replacement of the systemic atrioventricular valve in 22, and other miscellaneous procedures. The overall early mortality was 16%, but for the 29 patients operated on after 1986 early mortality was 3% (Figs 26A-9A,B). Follow-up for the 93 early survivors extended to 26.5 years (mean, 11.4 years). The overall survival was 77% ± 4% at 5 years and 67% ± 5% at 10 years. Late survival was adversely affected by prior operations, more severe preoperative functional class, and cardiac rhythm other than sinus. Reoperation was required for 39 patients (41%), most commonly for conduit replacement (n = 22) or surgery for the systemic atrioventricular valve (n = 13). Pacemakers were required before surgery in 3 patients, or at the

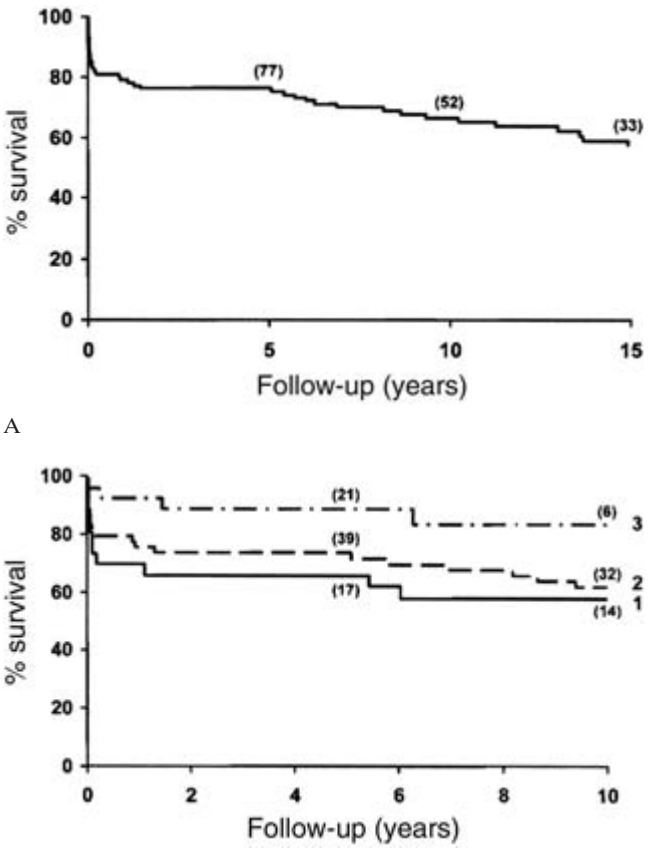

Fig. 26A-9 **A**. Kaplan–Meier survival curves for all 111 patients with congenitally corrected transposition of the great arteries undergoing operation at the Mayo Clinic from 1971 to 1996. The number of patients at risk at each 5-year interval is shown in parentheses. **B**. Kaplan–Meier survival curves for 111 patients stratified by time interval of operation. Group 1, 1971–76; group 2, 1977–86; group 3, 1987–96. The 5-year survivals for groups 1, 2, and 3 were 67% ± 9%, 74% ± 6%, and 90% ± 6%, respectively. (Reprinted from Biliciler-Denktas *et al.*,[113] Copyright (2001) Mosby Inc., with permission from Elsevier Inc.)

time of the operation, 10 patients. Within the first 30 days after surgery, 10 additional patients required pacemakers. Subsequent need for pacemakers in later follow-up was also common. Among the 68 patients alive at 30 days without a pacemaker, an additional 8 patients required pacemaker placement. At last follow-up, 19 (28%) of 67 survivors had pacemakers. As in the data from Toronto and elsewhere, progressive deterioration in right ventricular function and tricuspid valve function were common. Interestingly, patients with atrioventricular discordance and double-outlet right ventricle seemed to have lesser degrees of tricuspid valve regurgitation. The surgical mortality for the double-switch operation and early surgical follow-up data are encouraging. Indeed, in one series of 22 double-switch operations reported from the Cleveland Clinic in 2000, there was no early or late mortality.[102] In 1997, Reddy and his colleagues reported the early experience of the University of California in San Francisco group.[104] Of 11 patients undergoing a double-switch operation, they encountered one early and no late deaths. Stumper and Brawn reported in an editorial that their group from the Birmingham Children's Hospital had performed a double-switch operation in 32 patients with 1 early and 1 late death.[99] A somewhat earlier experience was reported by Yagihara and his colleagues in 1994.[95] Of 10 double-switch operations and a follow-up of only 4 years, they encountered 1 early and 2 late deaths. Imai and his colleagues from the Heart Institute of Japan, Tokyo Women's Medical Hospital have also had a substantial experience with the double-switch operation, reporting on 44 patients in 1997.[90,108] All but 4 patients survived the operation, with a hospital mortality of 9.1%, with a mean follow-up of 3.0 ± 2.2 years. Jahangiri and colleagues have made a case for anatomic correction in atrioventricular discordance by observing the effects of surgery on tricuspid valve function on 97 patients.[114] They observed that after pulmonary artery banding in 26 patients tricuspid valve function improved, while after the Blalock–Taussig shunt in 28, the severity of tricuspid regurgitation worsened. After physiological repair, there was no immediate improvement or worsening of tricuspid valve function, but later tricuspid valve repair/replacement was required in some patients. The operative mortality for the 70 patients undergoing physiological repair was 7%, while no operative mortality was encountered in the 19 patients undergoing anatomic repair. Ilbawi and his colleagues have recently extended their experience with anatomic repair of double discordance to 12 patients.[115] Two of these patients underwent Mustard and arterial repair, while the majority underwent Mustard and Rastelli-type operations. The mean age for the entire group was 9 ± 3.6 months. There was one death and only one patient required pacemaker therapy. The UK Birmingham Children's Hospital has recently published its experience with various forms of double switch operations in patients with atrioventricular discordance, addressing midterm results.[101A] Between November 1991 and June 2001, a total of 54 patients (median age 3.2 years, range 7 weeks–40 years) with either congenitally corrected transposition of the great arteries (n = 51) or atrioventricular discordance with double-outlet right ventricle (n = 3) underwent anatomic repair. This comprised a Senning procedure in all patients plus a classic arterial switch (double-switch group) in 29 cases (53.7%), plus a Rastelli procedure (Rastelli–Senning group) in 22 cases (40.7%), and plus intraventricular rerouting (Senning-tunnel group) in 3 cases (5.6%). Left ventricular training by pulmonary artery banding was performed before the double-switch operation in 9 of 29 cases (31%). The follow-up is complete (median 4.4 years). The early mortality was 5.6% (n = 3), with 2 late deaths. Kaplan–Meier survivals ± SEM) were 94.4% ± 3.1% at 1 year and 89.7% ± 4.4% at 9 years. Survivals at 7 years were 84.9% ± 7.1% in the double-switch group and 95.5% ± 4.4% in the Rastelli–Senning group (P = 0.32). Of the 49 survivors, 46 (94%) were in New York Heart Association functional class I. Six have acquired new left ventricular dilatation or impaired systolic ventricular function. Four patients in the double-switch group developed moderate aortic valve regurgitation, with 2 requiring valve replacement. Overall freedoms from reoperation at 1 and 9 years were 94.2% ± 3.3% and 77.5% ± 9.0%, with no significant difference between the groups (P = 0.60). Data published from Rutledge and her colleagues on the outcomes of 121 patients with double discordance also support consideration of the double-switch as an alternative to physiological repair.[115A] Replacement of the systemic tricuspid valve may be of benefit to some patients, while others will continue to demonstrate deterioration in right ventricular function.[116,117]

Beauchesne and colleagues have recently reported the outcome of the unoperated adult patients with congenitally corrected transposition of the great arteries.[118] They identified 44 patients aged from 20 to 79 years (mean 44 years) who had not had prior surgery, and in 29 the correct diagnosis was made ≥ 18 years ago. These patients were followed up to 144 months. Fourteen patients did not undergo surgery and 13 were alive at the last follow-up with 1 sudden death. Thirty patients required surgical intervention, and again at last follow-up, 29 were alive and 1 died from a noncardiovascular cause. All 30 patients undergoing surgery required replacement of the systemic atrioventricular valve because of severe regurgitation. One patient underwent at age 32 years a double-switch (Mustard and Rastelli) as well as replacement of the systemic atrio-ventricular valve. While there were no early postoperative deaths, 2 patients required pacemaker implantation because of postoperative heart block, and 3 other patients required internal defibrillators. Four of the 30 operated patients eventually required orthotopic heart transplantation because of systemic ventricular failure.[118] The most common hemodynamic problem encountered in this cohort was significant systemic atrioventricular valve regurgitation in the setting of impaired function of the systemic morphologically right ventricle. One of the issues faced by the Mayo Clinic in treating these patients was that in 53% of the patients, the referral for surgery was inappropriately delayed.[118]

Connolly and her colleagues have addressed the issue of pregnancy among women with double discordance.[119] Twenty-two women had 60 pregnancies resulting in 50 live births (83%). There were 11 unsuccessful pregnancies. One patient had multiple pregnancy-related complications, and there were no pregnancy-related deaths. The mean birth weight of the infants was 3.2 ± 0.4 kg. None of the 50 live offspring has been diagnosed with congenital heart defects.[119]

In the follow-up of these patients whether unoperated or operated with conventional surgical techniques, they must be scrutinized for the following issues:[12]

- abnormal rhythm and complete heart block
- function of the systemic atrioventricular valve
- function of the systemic right ventricle
- function of morphologically left ventricle to pulmonary artery conduit
- pulmonary artery branch stenosis (after previous shunt or conduit surgery).

If the patient has undergone a classic double-switch operation with an atrial repair of the Mustard or Senning type and an arterial switch operation, then surveillance for the typical baffle obstructions and leaks, and rhythm disturbances of atrial inversion surgery, and the panorama of complications subsequent to the arterial switch procedure must be defined (see Chapters 25A and 25B). One would still focus attention on myocardial performance and atrioventricular valve function as well. The potential complications of an atrial switch operation and ventricular switch include many of the issues just summarized above, but as well the potential for systemic outflow tract obstruction, etc.[12] One should also remember that some patients with double discordance may be at risk for tracheal compression secondary to the elongated aorta.[120]

In summary, the entity known as congenitally corrected transposition of the great arteries has a long and interesting history:

- Patients with this entity should not be considered "corrected."
- Frequent coexisting anomalies include ventricular septal defect, pulmonary outflow tract obstruction, and an Ebstein-like malformation of the morphologically tricuspid valve.
- The unique disposition of the specialized conduction tissue predisposes these patients to spontaneous onset complete heart block or surgically induced complete heart block.
- The De Leval convention has reduced surgically induced heart block subsequent to VSD closure.[30]
- The morphologically right ventricle supports the systemic circulation.
- Late right ventricular dysfunction and tricuspid regurgitation occur in both operated and non-operated individuals with double discordance.
- The classic surgical operation confers a physiological repair as the morphologically right ventricle retains its function as the systemic ventricle.
- An anatomic repair is more complicated, but advantageous as the morphologically left ventricle becomes the systemic ventricle.
- Anatomic repair can be achieved by:
  atrial and arterial switch operations in those patients without important pulmonary valvular stenosis
  atrial and ventricular switch operations in patients with ventricular septal defect and pulmonary outflow tract stenosis/atresia
- Ventricular switch surgery may require VSD enlargement.
- Patients with congenitally corrected transposition of the great arteries, unoperated, operated with either a physiological or anatomic repair require life-long cardiac surveillance.

Isolated Atrioventricular Discordance

Isolated atrioventricular discordance is an uncommon cardiac malformation usually producing cyanosis in the neonate and first well described by Van Praagh and Van Praagh in 1966, although earlier descriptions of this entity had been recorded.[1,2] The initial documentation of this rare disorder by Ratner and his colleagues was noteworthy as well for the association with dextrocardia. This unusual anomaly has been designated both isolated ventricular inversion and isolated atrioventricular discordance. The latter designation focuses on the fundamental nature of the disorder: a discordant atrioventricular connection, but a concordant ventriculoarterial connection or normal arterial connections (Fig. 26B-1). In patients with normal atrial arrangements or solitus atria, the morphologically right atrium receiving the superior and inferior caval veins and coronary sinus connects through a mitral valve with the morphological left ventricle. This left ventricle supports a concordantly connected aorta, usually with mitral–aortic fibrous continuity. The left atrium receiving the pulmonary veins connects with the morphological right ventricle through a tricuspid valve with its normal septal attachments, and the right ventricle supports the pulmonary artery. The pulmonary valve and the tricuspid valve are not in fibrous continuity. Thus this uncommon congenital cardiac anomaly produces "transposition" physiology, two circulations in parallel rather than in series, but importantly without the fundamental anatomy of transposition of the great arteries.[1–13] The designation of isolated atrioventricular discordance focuses on the nature of the connections and thus these patients should elicit the same concerns as the patient with so-called double-discordance or congenitally corrected transposition of the great arteries.

An extensive literature has described the basic morphologic substrate of isolated atrioventricular discordance.[1,2–30] This condition has been found primarily in patients with atrial situs solitus, but is well described in those with mirror-image atrial arrangements. The patient reported by Geva and his associates described as having atrioventricular alignment discordance with situs concordance had the uncommon finding of a right-hand pattern of internal organization of the morphologically right ventricle despite atrioventricular discordance.[17] This "discordancy" between atrioventricular connection and type of ventricular looping underscores the necessity of defining both the type of connection and the type of internal organization of the ventricle.[18–20] A similar patient has been reported by Sklansky and colleagues who commented on the superoinferior nature of the ventricular relationship, a tricuspid valve that was anterior and to the right of the pulmonary valve and the associated left juxtaposition of the right atrial appendage.[28]

Some reports have defined isolated atrioventricular discordance in patients when the atria are not clearly anatomically lateralized.[10,27,30] In such patients, it is likely that the atrial arrangement are that of left isomerism, but with lateralized or appropriate systemic and pulmonary venous connections. Being "segmentally correct" this type of patient does not fulfill the criteria for isolated atrioventricular discordance, although some would disagree with the concept of isomerism of the atrial appendages.[22] Isolated atrioventricular discordance makes no inference about the conal or infundibular anatomy. With concordant ventriculoarterial connections, the infundibular anatomy is often normal, although we have described patients with bilateral muscular infundibulum in this condition. In patients with isolated atrioventricular discordance in isolation, the clinical presentation is that of a newborn with transposition physiology and inadequate mixing at atrial level. By definition this would exclude patients with a double-inlet left ventricle, a left-sided rudimentary right ventricle (l-loop type double inlet left ventricle) and concordant ventriculoarterial connections.[23,24]

Those features in common with corrected transposition of the great arteries include (see also Chapter 30):

- a discordant atrioventricular connection
- an abnormal specialized atrioventricular conduction tissue with the potential for spontaneous onset complete heart block
- an abnormal morphologically tricuspid valve with dysplasia and displacement and functional regurgitation
- a ventricular septal defect, usually perimembranous outlet
- the potential for pulmonary outflow tract obstruction.

Associated cardiac malformations

The most common associated anomalies include a perimembranous outlet ventricular septal defect; atrioventricular septal defect;[7,27] pulmonary outflow tract obstruction; varying degrees of hypoplasia of the morphologically right ventricle; and regurgitation of the morphologically tricuspid valve.[26] In some patients the degree of right ventricular hypoplasia is so severe as to preclude a biventricular repair. Less frequently there is obstruction to the systemic outflow tract, with the subaortic area wedged between the right-sided ventriculoinfundibular fold and the infundibular septum. Regurgitation of the morphologically tricuspid valve may be very severe.[26]

Medical management

For the baby with isolated atrioventricular discordance without a large ventricular septal defect, the immediate management is

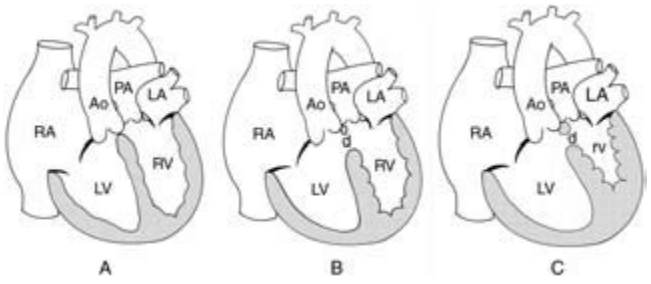

Fig. 26B-1 Isolated atrioventricular discordance. There is discordant atrioventricular connection but concordant ventriculoarterial connection, producing "complete transposition physiology." The ventricular septum may be intact (**A**) or associated with a ventricular septal defect (d) (**B** and **C**). The right ventricle is often hypoplastic, precluding biventricular repair. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV or rv, right ventricle.

to alleviate the hypoxemia reflecting inadequate atrial mixing. Thus the use of prostanoid therapy followed by an atrial balloon septostomy are the first lines of therapy.[26]

Surgical management

Some patients with isolated atrioventricular discordance with either normal atrial arrangements or inversus will be candidates for an atrial inversion procedure of either the Mustard or Senning type (see Chapter 25A).[10,14–16,26] These patients have the potential for nearly all of the mechanical complications of an atrial repair, including baffle leaks, superior or inferior caval vein obstruction; pulmonary venous obstruction; and sinus node dysfunction reflecting damage to the sinus node or its artery (see Chapter 29). Unlike patients with complete transposition, the morphologically left ventricle supports the aorta and the systemic circulation, and thus it is likely these patients will be spared late systemic ventricular dysfunction. In the baby with associated ventricular septal defect and important pulmonary outflow tract obstruction, a systemic-to-pulmonary artery anastomosis may be required, but if palliation can be deferred 4–6 weeks, then palliation with a bidirectional cavopulmonary connection could be considered (see Chapter 39). This maneuver makes the Mustard procedure technically easier because only the inferior caval vein needs to be baffled to the tricuspid valve and morphologically right ventricle.

One can thus define several surgical algorithms for the patient with isolated atrioventricular discordance:

1 Isolated atrioventricular discordance with two well-formed ventricles:
   Mustard or Senning and closure of ventricular septal defect if present (see Chapter 25A).
2 Isolated atrioventricular discordance and mild-to-moderate hypoplasia of morphologically right ventricle:
   Mustard or Senning and cavopulmonary shunt ($1^1/_2$ ventricle repair).
3 Isolated atrioventricular discordance, VSD, and severe pulmonary outflow tract obstruction:
   Mustard or Senning, ventricular septal defect closure;
   right ventricular outflow tract reconstruction/reconstitution.
4 Isolated atrioventricular discordance and severe hypoplasia of morphologically right ventricle or other anomaly precluding a biventricular repair:
   Stage to Fontan (see Chapters 35–37).

Outcomes

For patients with atrioventricular discordance and a biventricular heart, Yeh and his colleagues from Toronto have reviewed the outcome of the various forms of repair (see Chapter 30). The Kaplan–Meier curves for the patient with complete transposition with or without VSD are depicted in Chapter 29. The outcome and complications of the Fontan operation can be found in Chapters 36 and 37.

Anatomically Corrected Malposition of the Great Arteries

This "peculiar" terminology does not readily nor fully describe nor convey information about a group of hearts embraced by this designation. Furthermore hearts exhibiting anatomically corrected malposition of the great arteries cannot be repaired by one "general" surgical technique, as for instance tetralogy of Fallot, a malformation sharing in common a large malalignment ventricular septal defect, right ventricular outflow tract obstruction, etc. Van Praagh stated in an editorial in 1976 that: "Anatomically Corrected Malposition of the Great Arteries is hardly a household word, even among pediatric cardiology buffs."[1] There is a century-long history to this disorder, but Harris and Farber in 1939 described a *theoretically* abnormal relationship between ventricles and great arteries as anatomically corrected *transposition* of the great arteries.[2] This designation infers that each of the abnormally located great arteries originates above the anatomically correct or appropriate ventricle but with the aorta anterior to the pulmonary artery (Fig. 27-1). The benchmark anatomical descriptions of these entities by Van Praagh and Van Praagh in 1967 were still designated as "transposition," but because the great arteries are not really transposed, the nomenclature was revised to malposition in 1971.[3] The unusual relationship between the great arteries and the ventricles and the great arteries requires understanding of normal and abnormal infundibular development in the context of often complex forms of congenital heart malformations.[1,3–12]

The normal heart is characterized by a well-expanded subpulmonary infundibulum, and thus there is separation between tricuspid and pulmonary valves. The subaortic infundibulum is normally quite attenuated, thus bringing into close approximation the anterior leaflet of the mitral valve and the aortic valve. The disparity between the normally well-developed subpulmonary infundibulum and the attenuation of the subaortic infundibulum accounts in part for the more superior and leftward position of the pulmonary valve relative to the aortic valve in the normal heart.[3–8,13–19] In patients with so-called anatomically corrected malposition of the great arteries in its classical form, there is inversion of infundibular anatomy, or nearly so (Fig. 27-1).[20] That is, there is a well-defined or expanded subaortic infundibulum preventing aortic–mitral fibrous continuity, and the subpulmonary infundibulum is significantly attenuated, bringing the tricuspid valve closer to the pulmonary valve. In the patient with atrial situs solitus, concordant atrioventricular and ventriculoarterial connections and anatomically corrected malposition of the great arteries, the aorta is frequently levopositioned, but importantly without ventricular inversion or atrioventricular discordance.[1,3–12] If anatomically corrected malposition of the great arteries indicates a type of abnormal infundibular development (or maldevelopment), then it is possible that anatomically corrected malposition may be identified in patients with a wide range of segmental arrangements.[21,22] Anatomically corrected malposition of the great arteries has been frequently associated with left juxtaposition of the right atrial appendage. It can be seen also in the patient with isolated atrioventricular discordance (Fig. 26B-1).

Hearts with the fixed forms of subaortic stenosis often demonstrate aortic valve–mitral valve fibrous discontinuity.[15,16] Indeed, the degree of aortic–mitral separation in such patients may be very impressive, with the mechanism of aortic–mitral separation related to persistence of the left-sided ventriculoinfundibular fold. But in these patients the subpulmonary infundibulum is usually very well expanded, and the aortic valve is still usually posteroinferior to the pulmonary valve. Thus patients with the usual so-called short-segment or fixed forms of left ventricular outflow tract obstruction are not considered examples of anatomically corrected malposition of the great arteries.

Associated cardiac malformations

The commonly associated malformations are listed in Table 27-1.

In most clinical series, pulmonary outflow tract obstruction is perhaps more common than systemic outflow tract obstruction. Yet in patients with anatomically corrected malposition the subaortic infundibulum may be the substrate for subaortic stenosis. The ventricular septal defect frequently is of the infundibular-malalignment type with perimembranous-inlet extension. Dextrocardia is not uncommon as are abnormalities of the tricuspid valve. Because anatomically corrected malposition is infundibular maldevelopment, the spectrum of associated cardiac malformations is diverse.

Outcome analysis

There is no single medical or surgical algorithm that can be readily applied to patients with the infundibular anatomy of anatomically corrected malposition of the great arteries. Some patients may be candidates for a biventricular repair, while in others single ventricle palliation will be the only option (Fig. 27-2).

The long and frequently narrow subaortic infundibulum predisposes patients to a complex form of left ventricular outflow

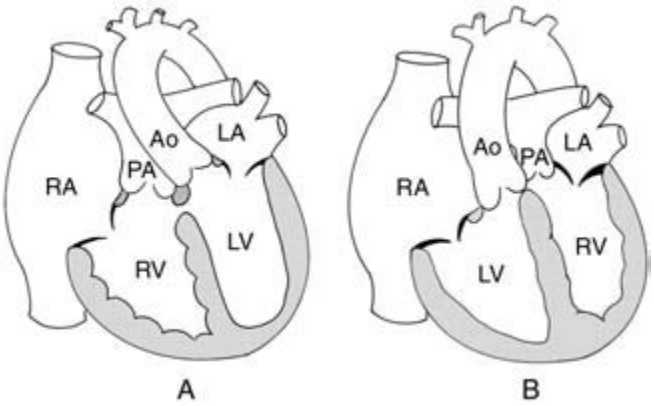

Fig. 27-1 Anatomically corrected malposition of the great arteries with concordant atrioventricular connection (**A**) and discordant atrioventricular connection (**B**). The left ventricle (LV) supports the aorta (Ao), but it is abnormally related with the pulmonary artery (PA) and there is subaortic infundibulum. LA, left atrium; RA, right atrium; RV, right ventricle.

Table 27-1 Anatomically corrected malposition of the great arteries

Fundamental nature of the disorder	1 Attenuated subpulmonary infundibulum and well-expanded subaortic infundibulum 2 Not transposition as pulmonary artery from right ventricle and aorta from left ventricle
Frequently associated anomalies	Ventricular septal defect Pulmonary outflow tract obstruction and/or left ventricular outflow tract obstruction Left juxtaposition of right atrial appendage Abnormalities of atrioventricular junction Levopositioned aorta without ventricular inversion

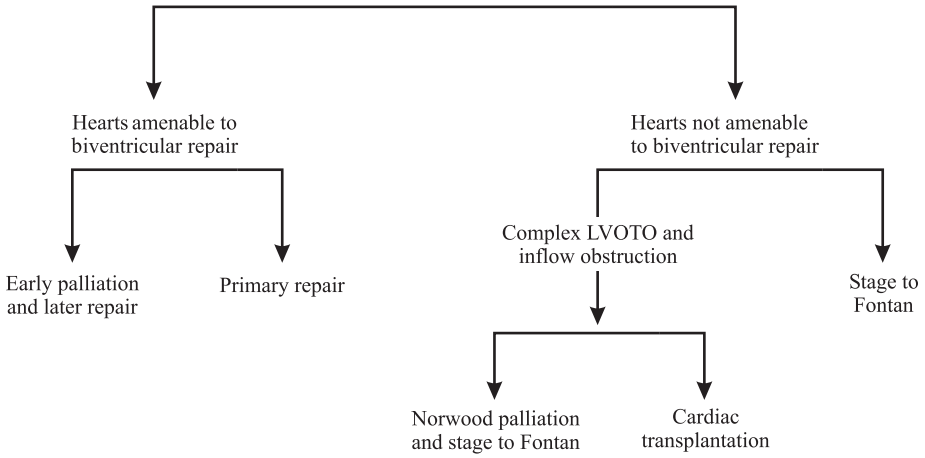

Fig. 27-2 Management of anatomically corrected position of the great arteries. LVOTO, left ventricular outflow tract obstruction.

tract obstruction, making a Norwood-type palliation likely in some neonates.[9,22–47]

Rittenhouse and his colleagues noted that the right ventricular outflow tract obstruction may be difficult to relieve with a transannular patch because the right coronary artery courses in front of the posteriorly-positioned pulmonary artery, thus necessitating a conduit repair.[30] The course of the right coronary artery had been noted by others, both in patients with anatomically corrected malposition and in double-outlet right ventricle with an l-malposed aorta[6,9,48,49] In late 2001, Morita and co-workers published a novel approach to repair the narrowed right ventricular outflow tract in three patients with anatomically corrected malposition of the great arteries in the setting of concordant atrioventricular and ventriculoarterial connections: atrioventricular groove patch plasty.[49] They took advantage of the fact that there is a leftward shift of the right coronary artery away from the right atrioventricular groove, and furthermore the atrioventricular conduction bundle has its normal posterior location.[49] These anatomic features permit a transannular subpulmonary incision of the right ventricular outflow tract between the course of the right coronary artery and tricuspid annulus. This novel approach was used successfully in 3 patients.[49]

Double-Outlet Ventricle

Part I: Double-outlet right ventricle

Apparently one of the earliest descriptions of a heart with origin of both great arteries from the right ventricle was that of Mr Abernathy, a surgeon at St Bartholomew's Hospital in London who first described such a heart in 1793.[1] A century later in 1893, Birmingham described a similar entity.[2] Braun and his colleagues in 1952, described a case in which "both the aorta and stenotic pulmonary artery originate from the right ventricle," and they went on to state that the "right ventricle serves as a 'double-outlet ventricle,' " perhaps one of the earliest designations of this entity.[3] Some attribute to A. Calhoun Witham the earliest introduction or use of the specific term "double-outlet right ventricle" which he considered a partial transposition complex.[4] There has been considerable discussion over the years as to how best to define this entity known as double-outlet right ventricle. As stated earlier, once considered a form of partial transposition, subsequently there seemed to be emphasis on the presence of bilateral muscular infundibulums or conus as the criteria for this diagnosis.[5–9] However this was not specific because bilateral muscular infundibulums were observed in some patients with complex forms of transposition of the great arteries, particularly those with an associated ventricular septal defect and left ventricular outflow tract obstruction and that peculiar entity now known as anatomically corrected malposition of the great arteries, amongst others.[10–17] There is now some consensus that double-outlet right ventricle is but one form of abnormal ventriculoarterial connection (Fig. 28-1).[18] While this definition is independent of infundibular anatomy, certainly infundibular anatomy is important to the understanding of the totality of this malformation.[7–9,18] Most would agree with the definition that this particular ventriculoarterial connection is characterized by the origin of 50% or more of the circumference of each great artery above the morphologically right ventricle, although some are less precise.[19] When both great arteries originate above the morphologically right ventricle and the ventricular septum is intact, there is no difficulty (nor disagreement) in defining the ventriculoarterial connection as double-outlet right ventricle.[20–28] However, an intact ventricular septum is very rare in this situation, and in most patients one or both great arteries are closely related or indeed override the ventricular septal defect, making the assignment of arterial connection difficult and imprecise.[29–40] As Roberson and Silverman pointed out in their echocardiographic study, malalignment of the ventricular septum (a "hockey-stick" configuration) also complicates the assignment of the ventriculoarterial connection as does the reality that the infundibular septum when present in hearts with double-outlet right ventricle does not partition the ventricles, but rather separates the arterial outlets.[41]

Incidence

The New England Regional Infant Cardiac Program recorded only 35 patients with double-outlet right ventricle of the 2251 infants with congenital heart disease surveyed by this study,[42] providing a prevalence of 0.033 per 1000 live births. Data from the Baltimore–Washington Infant Study defined a somewhat higher prevalence for double-outlet right ventricle of 0.056 per 1000 live births.[43] The Alberta Heritage study showed a prevalence for double-outlet right ventricle of 0.145 per 1000 live births.[44] This is considerably higher than that defined for either the New England Regional Infant Cardiac Program or the Baltimore–Washington study. The reasons for this difference remain unclear, and do not seemingly reflect different methodologies of diagnosis. The prospective Bohemia Survival Study identified 69 children with double-outlet right ventricle from 815, 569 children born between 1980 and 1990, giving a prevalence of 0.08 per 1000 live births. These accounted for 1.37% of all heart malformations encountered during this study.[45] The Pediatric Cardiac Care Consortium found a prevalence for double-outlet right ventricle of 0.035 per 1000 live births.[46] As with any conotruncal anomaly, there is the potential association with a chromosome 22q11 deletion and the clinical manifestations associated with this chromosomal abnormality.[47–50] Double-outlet right ventricle has been seen in association with a number of abnormal chromosomal abnormalities, but there does not appear to be any specific type of genetic predisposition. Finally, the ventriculoarterial connection of double-outlet right ventricle is particularly frequent in hearts exhibiting right isomerism.[51,52]

Morphology

Lecompte and his colleagues have presented an elegant and most informative surgical synthesis of double-outlet right ventricle based on their own evolving surgical experiences.[34] They suggest that the concept of ventriculoarterial connection is not perfectly clear in the definition of double-outlet right ventricle, raising several questions. Does this designation suggest that one ventricle ejects blood into one artery? Or does the ventriculoarterial connection of double-outlet right ventricle refer to an anatomic relationship between the ventricular cavity and the great arteries, or to the vessel alignment with the interventricu-

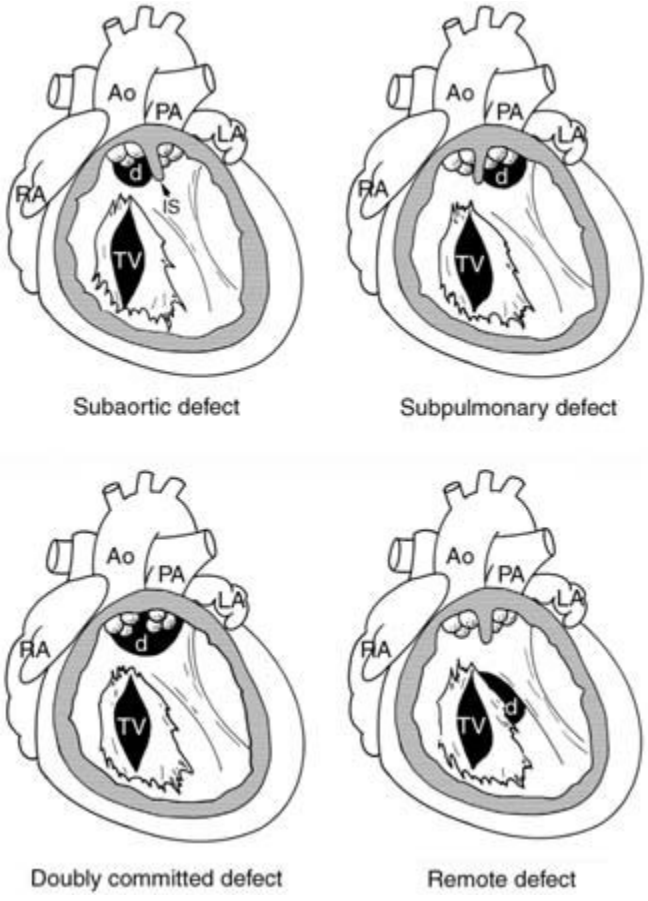

Fig. 28-1 Double-outlet right ventricle. The common denominator of double-outlet right ventricle is the origin of 50% or more of each great artery from the morphologically right ventricle. According to the proximity of the ventricular septal defect (d) to the great arterial valve, ventricular septal defects in double-outlet right ventricle can be classified into: subaortic defect; subpulmonary defect; doubly committed defect; remote or non-committed defect. Ao, aorta; IS, infundibular septum; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

lar septum, or to some amalgamation of these three concepts or visions of double-outlet right ventricle? Capuani and his colleagues have also recently presented an overview of the anatomic spectrum of abnormal ventriculoarterial connections and the surgical implications derived from these morphologic observations.[35] The emphasis of this paper is the location and insertion of the outlet or infundibular septum relative to the remainder of the muscular ventricular septum; appreciation of the extent of the of the inner curvature of the heart, the so-called ventriculoinfundibular fold; and the degree of formation of the posterior limb of the septal band. Observations about these structures are germane to the entire spectrum of conotruncal anomalies, some of which are characterized by abnormal transfer of the aorta from the left to the right ventricle. Whether one uses the definition of "double-outlet right ventricle" or "hearts with an abnormal ventriculoarterial connection" as the overarching definition, these designations do not provide any information about the situs, type of atrioventricular connection, internal organization of the morphologically right ventricle (i.e. right or left hand pattern), or the type of associated cardiac malformations. It is well known that among hearts with a double-outlet right ventricle, the situs may be normal, inverted, or not clearly lateralized (right or left isomerism).[18,38] The type of atrioventricular connection may be normal, discordant, absent right or left atrioventricular connection, or a double-inlet atrioventricular connection.[18,38,53–55] And the arterial roots may have a wide spectrum of spatial relationships, all despite the ventriculoarterial connection of double-outlet right ventricle.[37,56]

For many years, biventricular hearts with double-outlet right ventricle have been categorized by the position of the ventricular septal defect relative to the arterial outlets. This convention was first introduced by Lev and his colleagues in 1972 (Fig. 28-1).[36] Thus there are patients with double-outlet right ventricle with a subaortic ventricular septal defect; a subpulmonary ventricular septal defect, a ventricular septal defect committed to both arterial outlets (reflecting absence or significant attenuation of the infundibular septum), and finally a ventricular septal defect that is remote from either arterial outlet. These definitions are not strictly anatomic, but do convey physiologic/hemodynamic information. In the setting of biventricular hearts with double-outlet right ventricle, the most common associated malformations include either singly or in some combination ventricular septal defect, pulmonary stenosis, straddling and overriding atrioventricular valve, right ventricular outflow tract obstruction, and an obstructive anomaly of the aortic arch. Other associated anomalies include complete form of atrioventricular septal defect, juxtaposition of the atrial appendage, superoinferior ventricles, crossed atrioventricular connections, anomalies of systemic and pulmonary venous connections, ventricular hypoplasia, etc. The so-called Taussig–Bing form of double-outlet right ventricle has received considerable attention.[57–62] The ventricular septal defect is subpulmonary and bilateral muscular infundibulum prevents semilunar valve–atrioventricular valve fibrous continuity. In these patients the right ventricular outflow tract to the aorta is often narrowed; coarctation of the aorta is common; and straddling of the mitral valve is frequent as well.[63–83] The mitral valve may be cleft, not as in the atrioventricular septal defect, and may leak, promote outflow tract obstruction, compromise the ventricular septal defect and in some patients make a biventricular repair hazardous.[69] Beekman and colleagues have recently studied the morphological nature of the non-committed ventricular septal defect and associated anomalies in specimens with double-outlet right ventricle.[82] They categorize these ventricular septal defects as not directly committed, but opening into either the subaortic or subpulmonary outflow tract and those that are non-committed. In this latter group are the defects that are muscular inlet or atrioventricular septal defect without extension to the outlet.

Particular risk factors

For patients considered for a biventricular repair, anatomical concerns potentially complicating management include restrictive ventricular septal defects, multiple ventricular septal defects, straddling atrioventricular valves, cleft mitral valve with attachment of chordal apparatus to the infundibular septum, some degree of ventricular hypoplasia, and an obstructive anomaly of the aortic arch.[63–83] Complex coronary artery anatomy may be encountered in those patients undergoing the arterial switch operation,[74,84,85] but this factor has been over-

come with increasing experience with this operation (see Chapter 25B). An abnormal spatial relationship between the ventricles with a horizontal interventricular septum is frequent in patients with double-outlet right ventricle.[86,87,87A] There has been particular interest in the patient with double-outlet right ventricle and the complete form of atrioventricular septal defect, considered a remote form of ventricular septal defect.[88] Bharati and her colleagues in an autopsy study found in 507 specimens of complete atrioventricular septal defect only 34 with double-outlet right ventricle.[88A]

Outcome analysis

Because of the morphological heterogeneity of hearts with double-outlet right ventricle, an outcome analysis is difficult and complex. Some patients may clearly have a better outcome than others. As we have stated in earlier chapters, there is considerable experience with the fetal recognition of conotruncal abnormalities.[89–91] Hornberger and her colleagues reported on the outcome of 62 fetuses diagnosed with double-outlet right ventricle.[91] Termination of pregnancy took place in 34, two had a spontaneous intrauterine death, neonatal death occurred in 5 and 4 deaths occurred in infancy. The 17 survivors constitute 27.4% of the entire fetal cohort and 51% survival in the continuing pregnancies. Samanek and Voriskova reported on the outcome of the 69 children born with double-outlet right ventricle that were identified in the prospective Bohemia Survival Study.[45] More than 13% died in the first week after birth. In the first month of life the survival curve stabilized at 78.6% (95% CL, 68.3% to 88.2%). The decline did not stop until 3 years of age at an average survival rate of 47.8% (95% CL, 35.8% to 61.3%). Between 3 and 5 years, the curve decreased by only 2.9% and between the fifth and tenth years by 1.5%. The survival rate then remained at 43.4% (95% CL, 31.5% to 55.4%). It is quite surprising then to discover a woman at the age of 65 years with double-outlet right ventricle and unprotected pulmonary vascular bed.[92]

As with most forms of complex congenital heart disease, surgical therapy evolved from that of palliation to repair, with repair in earlier eras often preceded by some form of palliation.[93,94] Those patients with pulmonary hypertension and excessive pulmonary blood flow underwent pulmonary artery banding, while those with reduced pulmonary blood flow some form of shunting procedure to augment pulmonary blood flow. The patient with Taussig–Bing form of double-outlet right ventricle often required pulmonary artery banding and an atrial septectomy to facilitate mixing or after 1966 balloon atrial septostomy. Patients with double-outlet right ventricle and a subpulmonary ventricular septal defect, i.e. those with transposition physiology, benefited after 1963 from Mustard's form of atrial inversion surgery with closure of the ventricular septal defect (see Chapter 25A). Repair of double-outlet right ventricle with a subaortic ventricular septal defect was first achieved in 1957[95] and repair of double-outlet right ventricle with a subpulmonary ventricular septal defect in 1962.[96] Intraventricular rerouting was introduced by Kawashima *et al*. in 1971 for double-outlet right ventricle with a subpulmonary ventricular septal defect (Fig. 28-2).[97,98] It was in the late 1970s that repair of the double-outlet right ventricle with a remote ventricular septal defect was reported.[99] Stewart and his colleagues from the University of Alabama reported in 1979 the results of

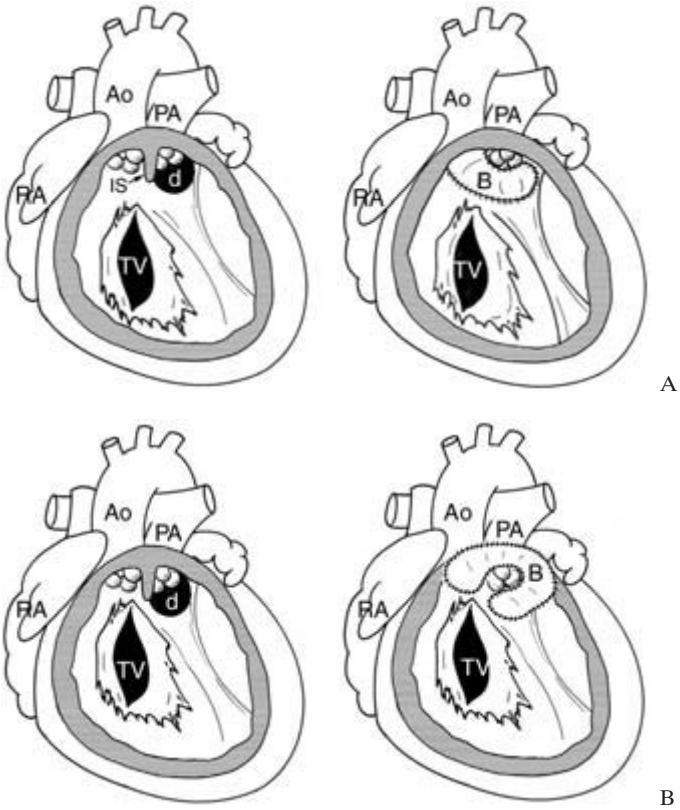

Fig. 28-2 Intraventricular rerouting in double-outlet right ventricle with subpulmonary ventricular septal defect. **A**. When the distance between the tricuspid valve (TV) and the pulmonary valve allows unobstructed intraventricular rerouting, the baffle (B) can be placed between the two valves with resection of the infundibular septum (IS). **B**. When the tricuspid and pulmonary valves are too close, the baffle should be placed around the anterosuperior margin of the pulmonary valve (Kawashima procedure). Ao, aorta; d, ventricular septal defect; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

repair from 1967 to 1978 of double-outlet right ventricle in 62 patients.[94] In this review, the overall surgical mortality was 34%. The risk was considerably lower for those with a subaortic ventricular septal defect and higher for those with a subpulmonary or remote defect. These repairs were carried out before the arterial switch operation was incorporated into the surgical algorithm.[94] Kirklin and his colleagues extended these observations by reporting in 1986 an 18 year experience with repair of double-outlet right ventricle in 127 patients.[100] The overall actuarial survival for the entire cohort was 38% at 12 years. In some subsets of patients it was much better, with an early survival at 2 weeks for repair of double-outlet right ventricle and subaortic ventricular septal defect of 99% and a 10 year survival of 97%. Results were also quite good for repair of double-outlet right ventricle and a doubly committed ventricular septal defect, but again the results in this era were poor for those patients with double-outlet right ventricle and either a subpulmonary or remote ventricular septal defect.[100] Indeed, in the current era most experiences suggest an excellent outcome and freedom from reintervention for patients with double-outlet right ventricle and subaortic ventricular septal defect ± pulmonary outflow tract obstruction.

With increasing surgical experience, it became possible to perform a biventricular repair in most patients with double-outlet right ventricle, including those with a remote ventricular septal defect and many with straddling atrioventricular valves. As pointed out by Uemura and others, the orientation of the ventricular septal defect needs to be precisely determined if the ventricular outflow tracts are to be properly reconstructed, thus avoiding obstruction across either the newly created subpulmonary and subaortic channels.[101] The subaortic pathway tends to be long and tortuous in those patients with a non-committed ventricular septal defect and also in those with a subpulmonary ventricular septal defect when a Kawashima intraventricular rerouting procedure is considered.[97,98] Attachment of chordal apparatus to the infundibular septum can also interfere with optimum construction of the intraventricular pathway to the aorta,[32–35,71–74,76,77,102] although various approaches to surgery of the infundibular septum have been employed to avoid this complication.[103–105] In the current era, two operative strategies have been employed for the correction of the double-outlet right ventricle with subpulmonary ventricular septal defect. These are the arterial switch operation often advocated when the great arteries are in an anteroposterior spatial relationship and for the patient with side-by-side great arteries, the Kawashima intraventricular repair (Fig. 28-2).[61,71–79,106,107] The approach of using the Mustard repair with closure of the ventricular septal defect has been abandoned largely because of the poor mid- and long-term outcome of these patients who experienced a substantial incidence of poor right ventricular function, congestive heart failure and sudden death (see Chapter 25A). We have stated earlier that the right ventricular origin of systemic outflow tract with obstruction seemed early on a risk factor for a biventricular repair.[71] The etiology of the systemic outflow tract obstruction was largely related to rightward and anterior displacement of the infundibular septum.[56,62–64,71–74,77–79] Some advocated a Damus–Kaye–Stansel approach to obviate this complication.[108–115] This necessitated closing the ventricular septal defect to the pulmonary orifice; dividing the main pulmonary trunk and connecting the proximal main pulmonary trunk to the ascending aorta; then a conduit was interposed between the morphologically right ventricle and the distal pulmonary trunk. The disadvantage to this procedure was that it required a conduit and the potential for thrombosis in the aortic root.[112] Some felt that this procedure could distort the semilunar valves, promoting valvular insufficiency.[116] We reported almost a decade ago our results with the Damus–Kaye–Stansel operation in 9 patients with the Taussig–Bing malformation.[115] Three patients did not survive the operation. The survivors have all required conduit replacement. Semilunar valve incompetence was common both before and after the operation, but most did not progress in severity. From our own experience and from that in the literature, this approach has largely been abandoned in favor of either the arterial switch option or intraventricular rerouting.[72–76,97,98,106]

There are some data indicating a strong association between side-by-side great arteries and unusual coronary artery patterns.[84,85] Uemura and his colleagues found that a single coronary artery was present in 27% of hearts with double-outlet right ventricle and side-by-side great arteries.[84] Similar findings had been published a few years earlier by Gordillo and colleague.[85] Mavroudis and his colleagues reported on a modest series of patients with the Taussig–Bing anomaly repaired by one of these two methods with excellent early and intermediate results for both methods.[106] Serraf and his colleagues from the Marie Lannelongue Hospital reported on 27 consecutive patients who underwent anatomic repair of the Taussig–Bing malformation between 1978 through 1990.[79] Seven patients underwent an intraventricular rerouting operation of the Kawashima type and 20 patients underwent an arterial switch repair with ventricular septal defect closure. The great vessel relationship was in a "d-transposition" relationship in 12 patients and side-by-side in 15. Seventeen patients had undergone a previous palliative operation. There were two early deaths, one in each group. The patient who died early after the intraventricular rerouting had severe left ventricular outflow tract obstruction which was attributed to non-resection of the infundibular septum. The other death which occurred in the arterial switch group was related to a right coronary ostial stenosis.[79] Reoperations were required in 7 patients, 2 in group 1, and 5 in group 2. There were two late deaths, one in each group. One patient died with severe left ventricular outflow tract obstruction and recurrent pulmonary infections and the other following a heart transplant required because of progressive myocardial ischemia. Actuarial survival and freedom from reoperation at 5 years were 73 ± 14.6% and 58 ± 13% (70% CL) respectively.[79] Lacour-Gayet and his colleagues extended these observations in 1997 with their publication addressing biventricular repair in 103 patients operated on between 1984 and 1996 with conotruncal anomalies with associated aortic arch obstruction.[78] Thirty-two of these patients had double-outlet right ventricle with subpulmonary ventricular septal defect. Twelve of these 32 patients underwent a two-stage repair with 4 early deaths, while 20 underwent a one-stage repair with 2 early deaths. Indeed, in the consideration of the entire cohort of 103 patients, the two-stage mortality was 27%, while the hospital mortality for a single-stage repair was 12%, and this fell even further to 9.4% in the last 3 years of the clinical experience.[72,78]

Masuda and colleagues reported on the results of the arterial switch operation performed in 27 patients with double-outlet right ventricle with subpulmonary ventricular septal defect between 1986 and 1997.[75] The great artery relationship was nearly anteroposterior in 15 and mostly side-by-side in 12. There was one operative and three late deaths. The predicted Kaplan–Meier survival at 9 years was 83 ± 8%. Freedom from reoperation was only 46 ± 20% at 9 years, with much of the need for reintervention occurring early in the clinical experience.[75] Takeuchi and colleagues in 2001 reported on the outcomes of 20 patients who underwent an arterial switch repair of double-outlet right ventricle with subpulmonary ventricular septal defect between 1992 and 1999.[73,74] Nine of the 20 patients had undergone some form of palliation before the arterial switch operation. Three patients had side-by-side great arteries, 10 had unusual coronary artery patterns, five had multiple ventricular septal defects, 5 had a hypoplastic aortic arch and 7 coarctation of the aorta.[74] Four patients died early after surgery. Their analysis indicated that side-by-side great vessel anatomy was identified as an independent risk factor by Cox multivariable regression analysis. Estimated one-year survival was considerably worse for those with side-by-side great arteries (72% [70% CL, 58% to 86%]) compared with patients with other great artery spatial relationships (70% CL, 90% to 100%) ($P = 0.05$, log-rank test). Two of the deaths were also directly related to

difficulties encountered with coronary artery transfer in infants with an unusual coronary artery pattern and side-by-side great arteries. One of these patterns was an inverted coronary pattern and the other was the left anterior descending coronary originating from the right coronary artery.[74]

An obstructive anomaly of the aortic arch is also well known to be commonly associated with the Taussig–Bing form of double-outlet right ventricle.[37,56,63–65,71–80] These include aortic arch hypoplasia, coarctation of the aorta, aortic arch atresia, or interruption. There is now considerable experience with biventricular repair of conotruncal anomalies associated with aortic arch obstruction.[78] Comas and his colleagues from the Royal Children's Hospital in Melbourne, Australia, showed that in their experience aortic arch obstruction does not influence or disadvantage the arterial switch repair option for the patient with the Taussig–Bing malformation.[80] Lacour-Gayet and his colleagues have had an extensive experience of biventricular repair in 103 patients with conotruncal anomalies associated with aortic arch obstruction.[78] Among these patients were 32 with double-outlet right ventricle and subpulmonary ventricular septal defect. The twelve year survival for this group was 72%. This compared to 100% survival for those with an arch obstruction in the setting of transposition of the great arteries and an intact ventricular septum and 80% survival for those with transposition and ventricular septal defect.[78] In the same review, the actuarial survival for those treated with one-stage repair was 83%, and 71% with a two-staged approach.

Kleinert and colleagues reviewed the anatomic features and surgical strategies in 193 children with double-outlet right ventricle and assessed the risk factors for early mortality.[117] These patients underwent surgery between 1978 and 1993. The authors divided this large cohort into two groups: noncomplex patients (group 1) had atrioventricular (AV) concordance, a single ventricular septal defect (VSD), balanced ventricles, no straddling AV valves, and no major pulmonary artery anomaly. Group 2 (complex) comprised all remaining patients. Independent risk factors analyzed included location of the main VSD, presence of additional VSDs, coarctation, ventricular outflow obstruction, ventricular hypoplasia, age at operation, operation before 1985, previous palliation, and type of definitive operation. Of 193 patients, 117 were in group 1 and 76 in group 2. In 148 patients, biventricular repair was undertaken, including 111 of 117 group 1 patients and 37 of 76 group 2 patients. Early mortality was higher among group 2 patients undergoing biventricular repair than among group 1 patients (8 of 37 versus 4 of 111, $P < 0.005$) and higher than group 2 patients undergoing a Fontan procedure (none of 29, $P < 0.01$). Aortic arch obstruction, operation before 1985, and multiple VSDs were significant risk factors for mortality. Age < 1 month ($P < 0.05$) and multiple VSDs ($P < 0.005$) were independent risk factors after definitive repair. Up-to-date follow-up is available on 144 surviving patients, with 127 (88%) in New York Heart Association class I and the remaining 17 in class II. Overall 10-year survival probability was 81%, whereas probability of survival, free from reoperation (after definitive surgery), was 65% at 10 years. This group found that biventricular repair was achieved in most patients with double-outlet right ventricle with low risk. However in this experience, a Fontan procedure was associated with a lower surgical mortality in those with complex double-outlet right ventricle.

The group from the Marie Lannelongue Hospital in Paris has had a very extensive experience with the repair of all forms of double-outlet right ventricle.[71,72,76–79,81] They have employed strategies to accomplish a biventricular repair whenever possible. Belli and colleagues from this institution reported in 1998 the outcomes in 154 consecutive patients who underwent biventricular repair for double-outlet right ventricle from 1985 through 1996.[76] The presence of bilateral infundibular structures was the major inclusion criterion (142 patients). According to the relationship of the ventricular septal defect (VSD) to the great arteries, there were 86 patients with a subaortic VSD (56%), 45 patients with a subpulmonary VSD (29%), 18 patients with a noncommitted VSD (12%), and 5 patients with a doubly committed VSD (3%). Sixty-five patients (42%) had undergone previous palliative procedures. At repair, the median age was 10 months, and the median weight was 6.5 kg. Two main types of repair were used: intraventricular baffle repair ($n = 115$) and arterial switch operation with VSD-to-pulmonary artery baffle ($n = 39$). There were 14 hospital deaths (9%; 70% confidence limit [CL], 7% to 12%). The only significant risk factor for early death was the presence of congenital mitral valve anomalies ($P = 0.02$). Twenty-eight patients (18%) required 39 repeat operations. The repeat operation rate was higher in patients with associated VSD enlargement at baffle construction ($n = 29$; 19%) ($P = 0.01$). There were 6 late deaths (4%; 70% CL, 2% to 7%). Patients presenting with pulmonary stenosis constituted a low-risk group for global death ($P = 0.008$). The median follow-up was 52 months. Ten-year actuarial survival and survival with freedom from repeat operation rates were 86% and 62% (70% CL, 83% to 89% and 54% to 70%), respectively. Jacobs in an editorial[118] to this paper concludes his comments with the same question posed by Delius and his colleagues: "Is a high-risk biventricular repair always preferable to conversion to a single ventricle repair?"[119] Some have clearly answered that question.[120,121]

The same group with Belli again as first author reported in 1999 the outcome of 23 patients with a double-outlet right ventricle and non-committed VSD who underwent biventricular repair between January 1987 and December 1997.[122] Nine (39%) had undergone previous palliation. The median age was 20 months at the time of the repair and the median weight was 8.5 kg. Two main types of repair were used: intraventricular baffle repair ($n = 21$) and arterial switch operation with VSD to pulmonary artery baffle ($n = 2$). At repair, 12 (52%) patients required concomitant VSD enlargement. In two other patients presenting with restrictive inlet VSD associated with tricuspid attachments, crossing the subaortic pathway biventricular repair was abandoned at operation. There were two hospital deaths (9%, 70% CL: 3–19%). Eight patients (35%, 70% CL: 23–48%) underwent nine reoperations, six for subaortic stenosis. No late death occurred. At last visit, all patients were asymptomatic and only two had cardiac medication. On the basis of this experience, this group concluded that biventricular repair of double-outlet right ventricle with non-committed VSD was possible in the vast majority of cases with comparable results to other subsets of double-outlet right ventricle. However, after repair the subaortic region is at risk for development of stenosis. A similar experience was reported by Lacour-Gayet and his colleagues reporting the approach of tunneling the left ventricle through the non-committed ventricular septal defect to the pulmonary infundibulum and then performing the arterial switch.[122A] This was accomplished successfully in 10 patients with one non-cardiac death. This approach required superior enlargement of the ventricular septal defect to prevent subaor-

tic stenosis. Barbero-Marcial and his colleagues have advocated the advantages of multiple patches in the repair of double-outlet right ventricle with non-committed VSD,[123] an approach he and his group have taken in 18 patients. There were two early and three late deaths. The authors conclude that the use of multiple patches for biventricular repair of double-outlet right ventricle with non-committed VSD simplifies the operation,[123] indeed making the operation a reality where a one-patch technique seemed impossible.[124] One of the more difficult groups of patients includes those with double-outlet right ventricle and a complete form of atrioventricular septal defect.[71,72,76,81,88,117,117A,117B,119–122,125–129] Some of these patients can be managed with a biventricular repair, but others have advocated univentricular palliation.[119–122] Uemura and his colleagues reported the outcome of eight patients with double-outlet right ventricle and doubly committed ventricular septal defect.[101] Pulmonary stenosis was present in two patients and interruption of the aortic arch in a third patient. All patients survived intraventricular rerouting. Wilkinson reported in 2002 the surgical results of 23 patients with double-outlet right ventricle and the complete form of atrioventricular septal defect treated between 1978 and 1993 at the Royal Children's Hospital in Melbourne.[5] Using a variety of reparative and palliative techniques there was one death among 18 patients. Tchervenkov has reviewed the surgical strategies employed to correct double-outlet right ventricle and the complete form of atrioventricular septal defect.[128A] He facilitated repair by enlarging the ventricular septal defect anteriorly, a maneuver termed ventricular septal defect translocation. This allowed closure of the ventricular septal defect to the aorta and a conduit was used to treat the associated pulmonary outflow tract obstruction.

Subaortic obstruction may be present before operation and develop as a complication of repair.[15] We have summarized elsewhere those mechanisms responsible for preoperative systemic outflow tract obstruction.[15] The ventricular septal defect may be restrictive in some patients, more commonly when the defect is subaortic, but a subpulmonary defect may also be obstructive. In the setting of the Taussig–Bing form of double-outlet right ventricle, the right ventricular infundibular aortic outflow tract may be intrinsically narrowed, wedged between the ventriculoinfundibular fold laterally and medially by the prominent infundibular septum.[15] Serraf and his colleagues have reported their experience with 30 patients with preoperative subaortic obstruction complicating double-outlet right ventricle operated between 1981 and 1992.[117A] Using a variety of surgical techniques to alleviate the systemic outflow tract obstruction, there were two early and one late deaths. Actuarial survival and freedom from reoperation were 86.6% and 87%, respectively. In some patients not considered preoperatively to have a restrictive ventricular septal defect, left ventricular volume unloading operations may lead to early changes both in ventricular geometry and ventricular septal defect size.[117B] Cognizant of these observations, one should usually consider enlargement of the ventricular septal defect when possible, acknowledging especially when the ventricular septal defect is "borderline" in size, its potential to become smaller.

Surgical algorithms for patients with double-outlet right ventricle are summarized in Table 28-1.

In a separate paper from the Marie Lannelongue Hospital, Piot and his colleagues report the echocardiographic appearances of subaortic obstruction following correction of double-outlet right ventricle in 8 children reoperated between January 1994 and June 1996.[130] The initial repair of the double-outlet right ventricle was performed before 3 months of age in 6 patients. Those patients with subaortic ventricular septal defects (4 cases) and those with non-committed ventricular septal defects (2 cases) had been treated by tunneling between the left ventricule and the aorta, and those with subpulmonary ventricular septal defects (2 cases) by tunneling between the left ventricle and pulmonary artery and then performing the arterial switch operation. Reoperation for subaortic obstruction was performed after 18 to 33 months. The instantaneous maximal gradient measured by Doppler echocardiography ranged from 60 to 145 mmHg. The causes of the postoperative subaortic obstruction were stenosis of the tunneling patch ($n = 2$), subaortic fibrous ring ($n = 3$), muscular septal hypertrophy ($n = 1$), anterolateral muscular hypertrophy ($n = 1$), relics of tricuspid tissue inserted on the infundibular septum ($n = 1$). Subaortic obstruction was diagnosed in the echocardiographic subcostal views in all cases; the nature of the obstruction was determined in 6 of the 8 cases. The mechanism of obstruction by stenosis of the tunneling patch was only detected in 1 of the 2 cases. In this regard, cross-sectional echocardiographic imaging has largely replaced cardiac catheterization with angiography, especially in those who have not had prior palliation.[131] Hemodynamic investigation may still be necessary in those patients presenting late with unprotected pulmonary blood flow, and angiography may complement the echocardiographic examination in those patients with multiple ventricular septal defects, concerns about ventricular hypoplasia, or where there are specific concerns about coronary artery anatomy.[56]

Table 28-1 Surgical algorithms for patients with double-outlet right ventricle

Associated anomaly	Surgical approach
Subaortic ventricular septal defect	Primary repair
Subaortic ventricular septal defect and pulmonary stenosis	Treat like tetralogy
Subpulmonary ventricular septal defect	Arterial switch, or Kawashima
Doubly committed	Repair
Remote	Intraventricular repair or Fontan

One of the more difficult anatomic features complicating the management of the patient with double-outlet right ventricle is straddling of the atrioventricular valve.[66–71] In the presence of major straddling of an atrioventricular valve, most abandon a biventricular repair, opting instead for univentricular palliation.[119–121] Yet clearly biventricular repair has theoretical advantages because it has the potential for establishing normal anatomy and physiology. Since 1984, Serraf and his colleagues again from the Marie Lannelongue Hospital operated on 34 patients with double-outlet right ventricle ($n = 15$) or transposition of the great arteries ($n = 19$) with isolated straddling tricuspid valve ($n = 17$), isolated straddling mitral valve ($n = 9$), both mitral and tricuspid straddling ($n = 2$), or abnormal insertion of tricuspid ($n = 7$) or mitral ($n = 2$) chordae in the left ventricular outlet, precluding an adequate tunnel construction.[71] Straddling was categorized according to the location of the papillary muscle insertion in the opposite ventricular chamber: type A, on the edge of the ventricular septal defect ($n = 14$); type B, on the opposite side of the ventricular septum away from the

edge of the defect ($n = 8$); type C, on the free wall of the opposite ventricular chamber ($n = 8$). Abnormal chordal insertions were classified according to the location of their attachments around the edges of the defect. Three types of chordal distribution were identified: on the aortic conus, on the pulmonary conus crossing the ventricular septal defect, or around the defect closing it like a curtain. All but three patients had two ventricles of adequate size. Sixteen patients underwent palliation. Median age at the definitive operation was 6.5 months (range 1 to 130 months). Thirty patients underwent a biventricular repair and four had a univentricular repair. Biventricular repair was achieved by an arterial switch operation in 18 patients and by tunnel construction from the left ventricle to the aorta in 12. In isolated straddling of types A and B, the ventricular septal defect was closed by adjusting the septal patch on the ventricular side above the straddled papillary muscle. In type C, the patch was sewn over the papillary muscle by applying it on the septum. In double straddling, the ventricular septum was incised between the two papillary muscles, and an ellipsoid patch was used to reconstruct the septal defect, directing each subvalvular apparatus into its own ventricular chamber. When the abnormal chordae in the left outflow tract inserted on the aortic or pulmonary conus, the conus was incised and tailored to make a flap, leaving an unobstructed left ventricular outflow tract. In two patients the subvalvular apparatus was resected and reattached to the patch. Curtain-like chordae were a contraindication to biventricular repair in double-outlet right ventricle but not in transposition. There were four early deaths and one late death, all occurring in the group having biventricular repair. Death was due to myocardial ischemia ($n = 1$), right ventricular hypoplasia ($n = 1$), pulmonary hypertension ($n = 1$), and residual subaortic stenosis ($n = 1$). Two patients had moderate to severe postoperative atrioventricular valve incompetence, caused by a cleft in the mitral valve in one patient. Three patients were reoperated on for subaortic stenosis ($n = 1$), pulmonary stenosis ($n = 1$), and mitral regurgitation ($n = 1$). Mean follow-up of 30.7 ± 19.4 months was achieved in the survivors. All but one patient (univentricular repair) were in New York Heart Association class I, without atrioventricular valve incompetence. Actuarial survival at 4 years was 85.3% ± 3%. They concluded that straddling or abnormal distribution of chordae tendineae of the atrioventricular valves does not preclude biventricular repair in double-outlet right ventricle or transposition of the great arteries provided that the ventricles are of adequate size. Curtain-like abnormal tricuspid chordae remain a contraindication to biventricular repair in double-outlet right ventricle. Fraisse and colleagues have discussed the management and outcome of patients with abnormal ventriculoarterial connections and a cleft mitral valve.[69] Firstly, from their review of the literature, they state that mitral valve anomalies are identified and may complicate arterial repair in from 2.8% to 5% of patients. Also they state that in autopsy studies, the incidence of mitral valve anomalies is considerably higher, approaching 30%. They identified 21 patients operated on with a cleft mitral valve, abnormal ventriculoarterial connections, and two well-developed ventricles. The majority of patients in this experience had transposition of the great arteries. Eight patients had ventricular outflow obstruction due to the mitral valve, and 2 had more than mild mitral regurgitation. One patient required initial mitral valve surgery. Eleven patients underwent biventricular repair, associated with mitral valve repair in two cases: arterial switch operation ($n = 4$), Senning operation ($n = 3$) associated with an arterial switch operation in one case, intraventricular repair ($n = 3$), and Rastelli-type extracardiac conduit repair ($n = 1$). Single-ventricle palliation was performed in 10 patients with major straddling of the mitral valve ($n = 5$), outflow tract obstruction ($n = 2$), and noncommitted or multiple VSDs ($n = 3$). There were three hospital deaths, two of which occurred after biventricular repair and one after an early reoperation after a bidirectional cavopulmonary anastomosis. Postoperatively after biventricular repair, 1 patient required permanent pacemaker implantation and 3 patients were reoperated on for subaortic stenosis ($n = 1$) and mitral regurgitation ($n = 2$), with one late death. By multivariate analysis, patients with a double-outlet right ventricle were at greater risk of death ($P = 0.04$). After a mean follow-up period of 60.7 months (± 68.6 months), 16 patients are in New York Heart Association (NYHA) class I. One patient with a moderate mitral regurgitation on Doppler study is in NYHA class II. On the basis of this experience they concluded that the surgical management of this group of patients remains controversial. A biventricular repair may not always be feasible, especially in cases of complex intracardiac anatomy associated with major straddling of the mitral valve. Single-ventricle palliation can be achieved in these patients, although it is unknown whether the long-term results are as good as those obtained with biventricular repair.[69]

Tchervenkov and his colleagues from the Montreal Children's Hospital reported in 1995 the outcomes in 24 consecutive neonates and infants with double-outlet right ventricle and atrioventricular concordance (median age, 4 months) who underwent anatomic biventricular repair beginning in May, 1989.[132] One patient (4%) had undergone prior pulmonary artery banding but was still repaired as a neonate at 22 days of age. Twelve patients had a subaortic ventricular septal defect (VSD), 5 patients a subpulmonary VSD, 3 patients doubly committed VSD, and 4 patients a noncommitted VSD. Sixty-nine of 72 associated lesions were repaired simultaneously. Four types of repairs were used: intraventricular rerouting in 16 patients, arterial switch operation with VSD closure into the pulmonary artery in 4 patients, Rastelli-type repair with extracardiac conduit in 3 patients, and the Damus–Kaye–Stansel repair with concomitant repair of aortic arch obstruction in 1 patient. Ventricular septal defect enlargement was necessary in 15 patients. Repair of subpulmonary stenosis and of subaortic stenosis was carried out in 13 and 4 patients, respectively. Three patients underwent simultaneous repair of aortic arch obstruction with no mortality. Two of the patients with noncommitted VSD had simultaneous repair of complete atrioventricular canal and repair of severe pulmonary venous obstruction. The perioperative mortality was 8% (2 patients), and there was one late death (4%). Two patients (9%) underwent early successful reoperations (5 and 8 weeks postoperatively). The two reoperations were for residual VSD (1 patient) and severe mitral regurgitation (1 patient). All 21 survivors are alive at a mean follow-up of 40 months (range, 7 months to 6 years). The estimated 5-year actuarial survival was 88%, with no deaths after 2 months postoperatively. Ninety-five per cent of long-term survivors had no restriction of physical activities because of cardiac status and are receiving no cardiac medications.

Aoki and his colleagues from the Children's Hospital in Boston reported in 1994 a 10 year institutional experience with the repair of 73 patients with double-outlet right ventricle.[133] Five types of repair were used during the study period: intra-

ventricular tunnel repair, arterial switch with ventricular septal defect-to-pulmonary artery baffle, Rastelli-type extracardiac conduit repair, Damus–Kaye–Stansel repair, and atrial inversion with ventricular septal defect-to-pulmonary artery baffle. Overall actuarial survival estimate at 8 years is 81%. The presence of multiple ventricular septal defects and patient weight lower than the median were nearly significant risk factors for early mortality ($P < 0.06$). Nineteen patients (26%) required 24 reoperations. Patients with subaortic ventricular septal defects were significantly reoperation free ($P < 0.05$). Patients with noncommitted ventricular septal defects were at significantly higher risk for reoperation during the study period ($P < 0.05$). The prevalence of late right or left ventricular outflow obstruction in the non-subaortic VSD groups was concerning. The median age at repair in this series was 0.76 years, and there was a nonsignificant trend ($P = 0.13$) for early mortality in patients younger than 1 year of age. These patients tended to have other serious cardiac anomalies associated with double-outlet right ventricle that necessitated early operation. Wilkinson documented the Royal Children Hospital's results with surgical treatment of double-outlet right ventricle with multiple ventricular septal defects.[5] Twenty-three patients were treated with a variety of surgical procedures with 5 deaths.

Brown and his colleagues reported their 20-year (1980–2000) experience with the surgical repair of 124 patients with double-outlet right ventricle.[133A] Four basic types of repair were used in these patients including an intraventricular tunnel repair; use of a valved or non-valved conduit, an arterial switch repair for those with a subpulmonary ventricular septal defect, and staging to the Fontan. For the entire series, there were 6 early deaths (4.8%), 4 late deaths (3.2%) and 2 heart transplants (1.6%). The overall 15-year survival for those with an uncomplicated form of double-outlet right ventricle and a subaortic ventricular septal defect was 95.8%; for those with a subpulmonary ventricular septal defect, 89.7%; and for those with a complex form of defect, 89.5%. Freedom from reoperation for these three groups at 15 years was 87%, 72%, and 100%, respectively. This group found that the ventricular septal defect, was restrictive on preoperative investigation in only 2 patients, but ventricular septal defect enlargement by resection of the infundibular septum was performed in an additional 14 patients to improve the baffle geometry or to reduce the potential for late transseptal obstruction.[133A] In follow-up, residual left ventricular outflow tract obstruction was identified in 3 patients, 2 considered mild and moderate in one. Wu and his colleagues reported the excellent outcomes in 9 patients of primary repair of double-outlet right ventricle with left-malposition of the great arteries using a modified Rastelli repair.[133B] All patients had a subaortic infundibulum and a levopositioned aorta. Eight of the 9 patients had either valvular or subvalvular stenosis. The ventricular septal defect was subpulmonary in 3 and noncommitted in 6. There were no operative deaths and no injury to the right coronary artery that typically crosses the stenotic pulmonary outflow tract in front of the pulmonary valve.[133B]

Preminger and her colleagues first called attention in 1994 to a peculiar type of "intramural" residual ventricular septal defects seen after repair of conotruncal anomalies.[134] These departed from the more common postoperative ventricular septal defect which usually resulted from additional defects, patch dehiscence, or incomplete closure and lie in the septal plane. However, after a right ventricular aorta is baffled to the left ventricle, the ventricular septal defect patch and RV free wall form part of the systemic outflow tract. This "neo-left ventricular" outflow tract thus provides a potential location for residual interventricular communications which are out of the septal plane. In a relatively short period of time from June 1990 to October 1992, they observed such defects in 8 patients, 5–26 years old, after repair of double-outlet right ventricle ($n = 6$), tetralogy of Fallot ($n = 1$), or truncus arteriosus ($n = 1$). In each, the ventricular septal defect patch was anchored to the right ventricular free wall near the aortic root. None the less, channels were observed around the edge of the patch, between the neo-systemic outflow tract and the right ventricle. All patients had right ventricular hypertension; in seven, the pulmonary-to-systemic flow ratio (Qp:Qs) was ≥ 2. These defects were difficult to close, either surgically or with transcatheter umbrella closure, and two patients died. Belli and his colleagues reported in 2000 their experience with the residual intramural ventricular septal defect which they define as resulting from the insertion of the patch within the trabeculated right ventricular free wall related to the ventriculoinfundibular fold (Fig. 28-3).[135] This creates a communication through the intertrabeculated spaces to the right ventricular cavity. They had difficulty in exposing and repairing this type of defect through a right ventricular approach, but found the defects easy to close through the aortic root.[135]

One of the recurrent postoperative themes is that of subaortic stenosis (Fig. 28-4).[136] This complication has been documented after most forms of correction of double-outlet right ventricle, and is often related to the tortuous tunnel between

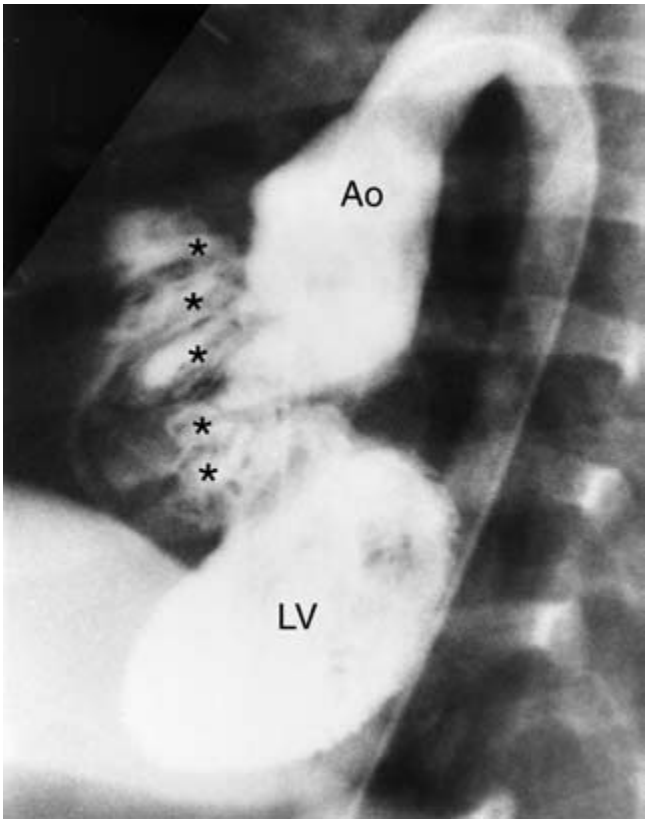

Fig. 28-3 Residual intramural interventricular defects. Postoperative left ventriculogram shows shunts through the residual defects flowing through the intertrabecular spaces in the right ventricle (asterisks). Ao, aorta; LV, left ventricle.

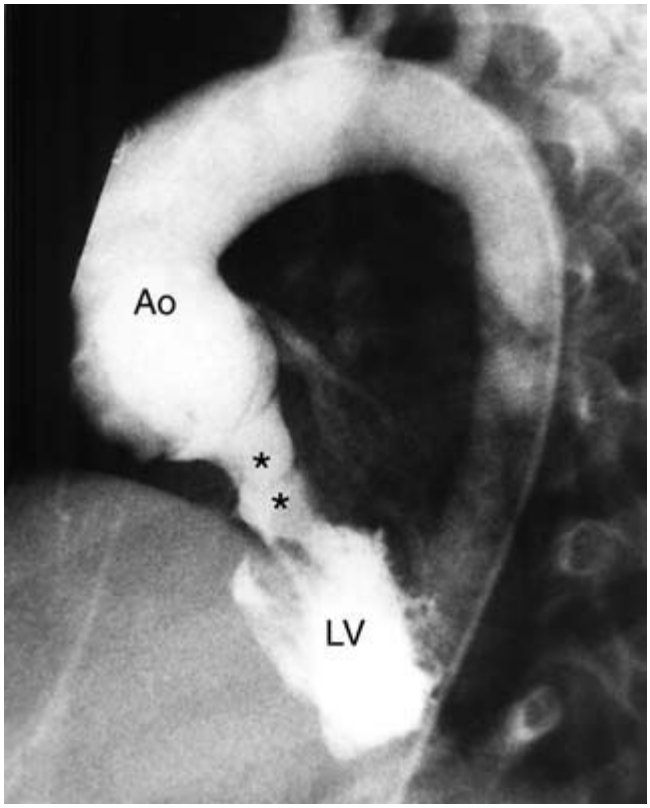

Fig. 28-4 Postoperative subaortic stenosis (asterisks) after repair of double-outlet right ventricle with a subaortic ventricular septal defect. Ao, aorta; LV, left ventricle.

the left ventricle and aorta.[71–74,76,79,81,98,106,117,122,123,124–130] Of 180 patients who underwent biventricular repair of double-outlet right ventricle at the Marie Lannelongue hospital in Paris, 9 (5%) required reoperation because of subaortic stenosis.[136] The median age at biventricular repair was 4 months. The subaortic stenosis was progressive, beginning with an immediate postoperative left ventricle to aortic gradient of 10 ± 10 mmHg and became 84 ± 27 mmHg over a mean interval of 45 ± 66 months. At reoperation the obstruction was caused by the protrusion of the inferior rim of the ventricular septal defect associated with subaortic hypertrophied muscle and fibromembranous tissue. The surgical technique to relieve the subaortic stenosis was an extended septoplasty. According to the authors,[136] an incision was made in the septal patch and was extended into the muscle towards the apex creating a large opening of the left ventricular outlet. A new patch was then positioned to streamline the left ventricular outflow tract. The extended septoplasty improved the left ventricular outflow tract obstruction and no patient died at reoperation.

Some patients including those with mitral atresia, major straddling of one or both atrioventricular valves, ventricular hypoplasia or double-outlet right ventricle with an intact ventricular septum may be candidates for single ventricle palliation.[119–121,137,138] Those patients with double-outlet right ventricle and an intact ventricular septum may have spectacular ventriculocoronary connections,[26] and may be at risk for adverse coronary artery events. The Fontan procedure, its varying staging maneuvers, and postoperative complications are considered in Chapters 35–37. For the outcomes of the atrial or arterial switch protocols which either have been or are applied primarily to the patient for double-outlet right ventricle with subpulmonary ventricular septal defect, please see Chapters 25A and 25B. In those patients undergoing intraventricular repairs, long-term issues are likely related to:

- residual intramural ventricular septal defects (Fig. 28-3)
- systemic outflow tract obstruction (Fig. 28-4)
- pulmonary outflow tract obstruction
- pulmonary regurgitation (for those undergoing "tetralogy-like" repair
- fate of the right ventricular–pulmonary artery conduit
- form and function of atrioventricular valves
- long-term problems related to pacemaker therapy
- damage to the right coronary artery.

In summary, what are the fundamental issues with hearts considered to have double-outlet right ventricle?

- The morphology is diverse, with abnormalities of situs, atrioventricular connection, size and position of the ventricular septal defect relative to the great arteries. The spatial relationships between the great arteries vary considerably as well.
- Particular confounding features include straddling and overriding atrioventricular valves, cleft mitral valve, systemic outflow tract obstruction, obstructive anomalies of the aortic arch, and multiple ventricular septal defects.
- Numerous surgical strategies have been employed to correct hearts with double-outlet right ventricle including atrial repair of the Mustard or Senning-type with closure of the ventricular septal defect; the Kawashima or Rastelli approach; arterial switch repair with closure of the ventricular septal defect; the Damus–Kaye–Stansel approach; multiple intraventricular patches.
- Some consider univentricular palliation in patients with complex forms of double-outlet right ventricle preferable to high risk biventricular repair.
- The Mustard–Senning approach with ventricular septal defect closure and Damus–Kaye–Stansel approaches are for-the-most-part obsolete and are no longer employed.
- The specific complication will depend in part on the surgical technique employed. Systemic outflow tract obstruction may occur at the VSD level as the left ventricle as tunneled to the aorta, or within the right ventricle itself.

Part II: Double-outlet left ventricle

Double-outlet left ventricle is a rare congenital cardiac anomaly characterized by origin of both great arteries, or more than 50% of each arterial root above the morphologically left ventricle.[1–7] Wilkinson suggests that double-outlet left ventricle accounts for only about 5% of all hearts with a double-outlet ventriculoarterial connection in the setting of a biventricular heart, corresponding then to an incidence of less than 1 in 200,000 births.[7]

In hearts where the interventricular septum is intact, the diagnosis can be readily established, without debate or discussion.[1,8,9] However when a ventricular septal defect is present, it is possible for one or both arterial orifices to override the ventricular septal defect, and then it may become more difficult to assign the ventriculoarterial connection. In the first case of double-outlet left ventricle well described by Paul and his colleagues and where the ventricular septum was intact, both the subaortic and subpulmonary infundibula or conuses were deficient.[1] Initially this feature was considered important in the

setting of double-outlet left ventricle. Some years later Van Praagh and colleagues studied infundibular development in 31 hearts with double-outlet left ventricle and a right-hand or D-ventricular loop, characterizing the infundibular anatomy as follows: a subpulmonary infundibulum was noted in 48%; a subaortic infundibulum in 26%; bilateral infundibuli were represented in 12%; and the infundibula were grossly deficient in 13%.[4] Thus the diagnosis of double-outlet left ventricle indicates an abnormality of ventriculoarterial connection, not an infundibular anomaly *per se*. Van Praagh and his colleagues considers three factors fundamental to the morphogenesis of double-outlet left ventricle.[3,4] In addition to the infundibular maldevelopment, hypoplasia of the morphologically right ventricle and malalignment of the conotruncus from the ventricle are seemingly important in the genesis of this disorder. Thus it is not surprising that disturbances of the right atrioventricular junction are defined in a considerable number of patients with this double outleft ventricle.[5] These abnormalities include tricuspid atresia, stenosis, straddling and override. Bharati and her colleagues have also called attention to the frequently observed abnormalities of the tricuspid valve and right ventricular underdevelopment in patients with double-outlet left ventricle.[5] Like the designation of double-outlet right ventricle, this diagnosis is independent of situs or atrioventricular connection.[3,6,7,10–12]

Manner and colleagues have identified double-outlet left ventricle in a chick embryo.[13] They found the anomaly leading to double-outlet left ventricle is a misalignment of the ventricular septum. The subarterial portion of the ventricular septum above the crista supraventricularis was not oriented in the normal oblique plane between the pulmonary and aortic valve, but is oriented in a frontal plane anterior to the origin of both great arteries. The consequences of this anomaly are the separation of the right-ventricular infundibulum from the origin of both great vessels (double-outlet left ventricle) and a lack of continuity between the malpositioned portion of the ventricular septum (posterior wall of the right-ventricular infundibulum) and a septum dividing the semilunar valve level. The infundibulum of the right ventricle is derived from the upstream portion of the embryonic conotruncus (conus) whereas the semilunar valves and great arteries are derived from its downstream protion (truncus arteriosus) and the aortic sac. Therefore, their findings suggest that the division of the conotruncus is performed by at least two different septa, one dividing the conus and another dividing the truncus arteriosus and aortic sac. The misalignment of the ventricular septum leading to this type of double-outlet left ventricle could result from a misalignment of the septal anlagen of the embryonic conus, the conus ridges. Interestingly, this malformation like other conotruncal malformations has also been identified in the dog.[14]

Associated malformations

The most exhaustive review of hearts with this condition has been carried out by Van Praagh and his colleagues in a report referred to earlier in this chapter.[3] They compiled 109 patients with this disorder, and subcategorized them into 8 anatomic types with two well-formed ventricles, and 7 anatomic types with only one well-developed ventricle. This analysis indicated that in those hearts with two well-formed ventricles, double-outlet left ventricle with a subaortic ventricular septal defect was the most common form, being identified in 62 of the 80 biventricular cases. They defined 4 subtypes of double-outlet left ventricle with a subaortic ventricular septal defect, with the most frequent of these, the so-called tetralogy-type. Less common are those forms resembling posterior transposition; transposition, ventricular septal defect with leftward aorta; and the form with aortic stenosis and coarctation. A subpulmonary ventricular septal defect was observed in 11 of the 80 biventricular hearts, and a doubly committed ventricular septal defect in 7. Other infrequent forms of double-outlet left ventricle with a biventricular heart include hearts exhibiting atrioventricular concordance with atrial situs inversus; atrioventricular discordance with situs solitus (the "corrected transposition" type); and atrioventricular discordance in situs inversus.[1–13,15–22] Tricuspid atresia is the most common anomaly of the atrioventricular junction in patients with a univentricular atrioventricular connection, occurring in 20 of 29 cases.[1,3,5,6,8,9,17,18] Ebstein's malformation of the tricuspid valve was observed in a few patients, and mitral atresia in one. Juxtaposition of the atrial appendages, abnormalities of systemic and pulmonary venous connections, and cor triatriatum have all been described in hearts with double-outlet left ventricle. Van Praagh and others have described double-outlet from the dominant left ventricle in patients with a univentricular atrioventricular connection.[2,3,20] Amongst those hearts with double-outlet left ventricle and an intact ventricular septum, the right ventricle is hypoplastic, and ventriculocoronary connections are present.[1,8,9]

Outcome analysis

There are too few such hearts to permit a meaningful outcomes analysis and there is little information about fetal recognition of this rare anomaly. While in the literature review carried out by Van Praagh and his colleagues more than a decade ago, 109 hearts with double-outlet left ventricle were identified,[3] this number has certainly increased. Yet no institution has had experience with a substantial number of these patients. Sakakibara. Pacifico, and Kerr and their respective colleagues reported the earliest experience with biventricular repair of a number of these patients.[23–25] The repair in this era usually consisted of closure of the ventricular septal defect, closure as well of the left ventricle-to-pulmonary artery pathway, and insertion of a right ventricle-to-pulmonary artery conduit. Some have been able to carry out a Fallot-type repair when the ventricular septal defect is subaortic and the spatial relationships between the great arteries are advantageous. There has been considerable discussion as to the optimum surgical approach in patients with double-outlet left ventricle.[26–28] For the most part, the particular surgical technique is dictated by the cardiac anatomy.[29–33] Although most biventricular repairs have utilized a conduit between right ventricle and pulmonary artery, some have successfully utilized the maneuver of pulmonary root translocation.[34–36] The downside of the conduit is the reality and necessity of conduit replacement. Pulmonary root translocation will leave the patient with pulmonary regurgitation and the long-term effects of this on the right ventricle have been discussed in Chapter 16. Imaging has evolved from angiocardiography to cross-sectional echocardiography and to magnetic resonance imaging.[37–45]

The thorough compilation of hearts with double-outlet left ventricle by Van Praagh reveals that at least 70% of such specimens are characterized by one developed ventricle, and are

thus candidates for univentricular palliation[3] (see Chapters 35–37). It is likely that some patients with only moderate tricuspid stenosis and right ventricular hypoplasia may be candidates for a one-and-a-half ventricle repair. In those patients with double-outlet left ventricle with an intact ventricular septum, ventriculocoronary artery communications may be conspicuous and may exact a toll of the left ventricle, analogous to some patients with pulmonary atresia and intact ventricular septum[1,8,9] (see also Chapter 30).

Robert M. Freedom and Shi-Joon Yoo

Tricuspid Atresia

Tricuspid atresia is an uncommon form of congenital heart disease, clearly less frequent than transposition of the great arteries, tetralogy of Fallot, or common arterial trunk. Unquestionably described by Kreysig in 1817,[1–3] the clinical features of tricuspid atresia were first characterized by Bellet and Stewart in 1933[4] and Taussig and Brown in separate publications in 1936.[5,6] In the classic form of tricuspid atresia, the situs is normal, the tricuspid valve is absent, and there is an obligatory right-to-left shunt at atrial level (Fig 29-1). The main ventricle is of left ventricular morphology and there is a right-sided rudimentary right ventricle communicating with the dominant left ventricle through a ventricular septal defect. When first described, the left ventricle supported the aorta and the hypoplastic right ventricle, the main pulmonary trunk. Thus the ventriculoarterial connections were concordant, or normal.

Incidence

The New England Regional Infant Cardiac Program (NERICP) provided a diagnostic frequency for tricuspid atresia of 0.057/1000 live births, although this probably slightly overestimates the frequency because of inclusion of left-sided atrioventricular valve atresias in the setting of a univentricular heart, L-ventricular loop-type.[7] The Baltimore–Washington Infant Study showed a lower prevalence at live birth of 0.039/1000 live births,[8] and data from the Pediatric Cardiac Care Consortium, a prevalence of 0.044.[7] Data from Toronto indicate a frequency for tricuspid atresia of 1/9956 live births or 1.2% of congenital heart disease.[10] There is little information on spontaneous fetal loss of babies with tricuspid atresia. Familial instances of tricuspid atresia have been reported.[9,11] Seven per cent of babies with tricuspid atresia in the NERICP had birth weights < 2.0 kg and 13% were considered to have severe extracardiac anomalies.[7] A rare case of tricuspid atresia has been associated with 22q11 deletion, and there is one report of tricuspid atresia and Ebstein's anomaly of the tricuspid valve in siblings.[11A,11B]

Morphology

One's understanding of both the morphology of tricuspid atresia as well as the natural history of patients with this disorder has evolved considerably over the past quarter century, precipitated in large part by Fontan's operation.[12] A number of morphologic expressions produce the physiology of tricuspid atresia; that is an obligatory right-to-left shunt at atrial level.[13–26] The classic morphological expression of tricuspid atresia is an absent right atrioventricular connection, rather than an imperforate one (Fig. 29-1). Characteristic of an absent atrioventricular connection is the absence of continuity, potential or otherwise, between the right atrium above and right ventricle below because atrioventricular sulcus tissue separates the floor of the right atrium and right ventricle (Figs 29-1A, 29-2).[13–26] A dimple is often observed in the floor of the right atrium, suggesting from the atrial perspective a potential connection between the atrium and ventricle.[20,21,26] This dimple, however, does not have potential connection with the rudimentary right ventricle and the atrioventricular connection is thus absent.[13–18,20,21,26] Interestingly, Wenink has examined microscopically the rudimentary right ventricle of patients with so-called classic tricuspid atresia, and there is some suggestion that even in patients considered to have an absent right atrioventricular connection that remnants of tension apparatus are present.[24] Less commonly the tricuspid valve will be imperforate with tensor apparatus interposed between a membranous or muscular imperforate tricuspid valve and the right ventricle (Fig. 29-1B).[27–37] Rarely, the morphologic basis for tricuspid atresia is an imperforate and displaced tricuspid valve, the imperforate Ebstein's form of tricuspid atresia.[36,37] In the classical expression of tricuspid atresia, the mitral valve connects with the morphologically and dominant left ventricle. The rudimentary right ventricle is right-sided and anterior, conforming to a d-ventricular loop.

The most common classification of tricuspid atresia, that originally proposed in 1949 by Edwards and Burchell, addressed both the type of ventriculoarterial connection and the clinical status of the magnitude of pulmonary blood flow (i.e. normal or concordant ventriculoarterial connections or discordant ventriculoarterial connections).[38] This classification has subsequently been revised to take into consideration those patients with a common arterial trunk (truncus arteriosus) as well as those patients with a univentricular heart of left ventricular type, L-loop pattern of internal organization, and an absent left atrioventricular connection.[39–42] The common and rare cardiac anomalies seen in the patient with tricuspid atresia have been fully catalogued. Some of these include atrioventricular septal defect; dextrocardia; anomalies of systemic and pulmonary veins; aortic atresia, fifth aortic arch; unroofed coronary sinus; divided left atrium; double-outlet ventricle; anatomically corrected malposition of the great arteries; juxtaposition of the atrial appendage, etc. Sanchez-Quintana and colleagues have studied the myoarchitecture and connective tissue in hearts with tricuspid atresia.[43] The overall architecture of the muscle fibers and its connective tissue matrix in hearts with tricuspid atresia

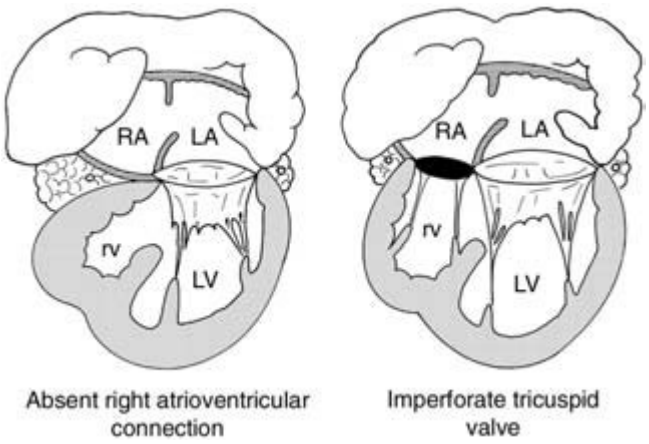

Fig. 29-1 Two forms of tricuspid atresia. It is more commonly due to absence of the right atrioventriuclar connection and much less commonly is an imperforate tricuspid valve. LA = left atrium; LV = left ventricle; RA = right atrium; rv = small right ventricle.

differs from normal with increased muscle and connective tissue. How this particular finding impacts on the long-term function of the left ventricle is unclear, but concerning.

Outcome analysis

Tricuspid atresia can be recognized in the fetus, as well as the usual coexisting abnormalities including ventricular septal defect, pulmonary stenosis and abnormalities of ventriculoarterial connection.[43A] Sharland has reported on the outcome of 84 fetuses with tricuspid atresia studied before the end of 1997.[43A] Twenty-two of these were found to have transposition of the great arteries and 7 of these 22 had aortic arch anomalies. Of the total group 54 sets of parents opted for termination of pregnancy; there were 2 intrauterine deaths, and 4 infant deaths.

Any number of clinical studies have attempted to define the natural and modified history of the patient with tricuspid atresia.[44–57] The outcome of patients with tricuspid atresia depends on the nature of the blood supply to the lungs and associated anomalies. Since the majority of patients with this condition have normal ventriculoarterial connections, and restrictive flow to the lungs, it is not surprising that progressive reduction in size of the VSD defines the clinical course of progressive cyanosis and the sequelae of hypoxemia.[58,59] Babies with tricuspid atresia and pulmonary atresia will usually present the earliest, coincident with ductal closure. About 20% of those with tricuspid atresia have a discordant ventriculoarterial connection or transposed great arteries.[59] Those without important pulmonary stenosis will usually die in infancy with congestive heart failure and pulmonary artery hypertension. This group tends to have an associated obstructive anomaly of the aortic arch, and this would of course accelerate clinical deterioration.

Until 1971, patients with tricuspid atresia with very reduced pulmonary blood flow were palliated with a variety of systemic-to-pulmonary shunts, and those past infancy with the classic Glenn or cavopulmonary shunt.[47–54] We reported on our early clinical experience with these shunts in 1975 and then in 1980.[50,51] The classic Blalock–Taussig shunt, Potts' shunt between the descending thoracic aorta and left pulmonary artery, Waterston shunt between the ascending aorta and right pulmonary artery were all used to augment pulmonary blood flow. The Potts' and Waterston shunts were often made too large, or grew, resulting in congestive heart failure and pulmonary artery hypertension. These shunts tended as well to distort by narrowing the pulmonary artery, often resulting in a substantially different pulmonary blood flow between right and left lung. Unfortunately, the complications of the Waterston and Potts' shunt, especially the propensity for causing pulmonary artery hypertension, excluded many of these patients from Fontan palliation.[60] Today, the Potts' and Waterston shunts are rarely used. None the less these shunts did provide acceptable palliation, and after all kinds of shunt, about 91% were alive 7 years after the shunting operation. For those patients with concordant ventriculoarterial connections and a very large ventricular septal defect, pulmonary blood flow could be controlled with banding of the main pulmonary trunk. However, most patients with concordant ventriculoarterial connections and increased pulmonary blood flow can be managed medically as the ventricular septal defect is usually only of moderate size and tends to narrow spontaneously.[59] Pulmonary artery banding could be used in the patient with discordant ventriculoarterial connections, and some of these patients required repair of an associated coarctation of the aorta. Progressive reduction in the size of the ventricular septal defect following pulmonary banding in those with transposition frequently resulted in systemic outflow tract obstruction (Fig. 29-3).[61–67] Data published some years ago from the Toronto Hospital for Sick Children showed that the classical Glenn shunt afforded excellent long-term palliation,[50–52] and in some of these palliation could be extended with creation of an axillary artery–vein fistula,[68] a maneuver first reported by Glenn and Fenn and others.[69,70] We reported our experience with this procedure in 11 patients.[68] Oxygen saturations generally increased and symptomatology improved, at the expense of course of volume loading the

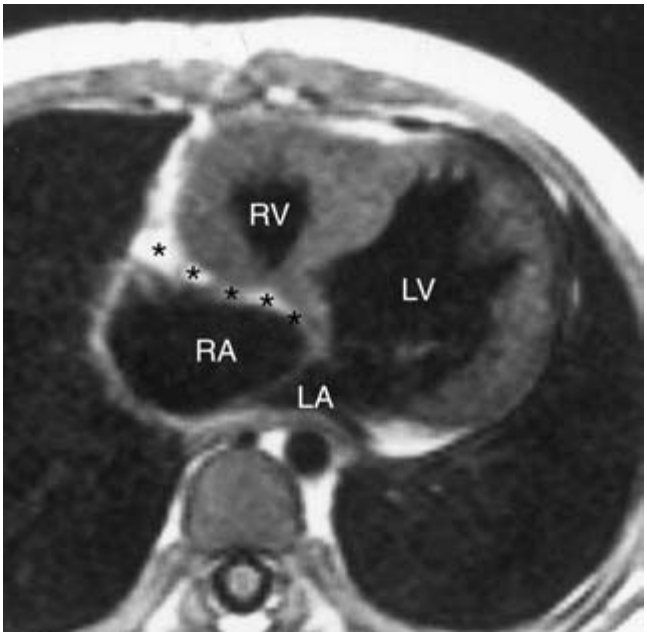

Fig. 29-2 Absent right atrioventricular connection seen in T1-weighted MR image. Notice that the epicardial fat tissue (asterisks) invaginates toward the center of the heart between the right atrium (RA) and the right ventricle (RV). LA = left atrium; LV = left ventricle.

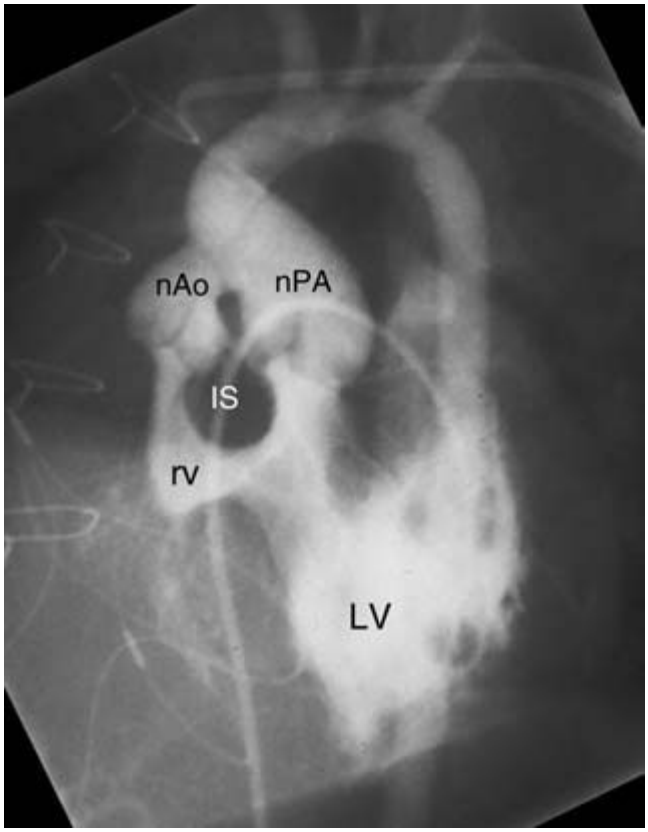

Fig. 29-3 Effect of pulmonary artery banding in a patient with tricuspid atresia with discordant ventrioculoarterial connection. The subaortic stenosis became severe with reduced size of the ventricular septal defect (d) and hypertrophy of the infundibular septum (IS). Damus–Kaye–Stansel operation was performed. LV = left ventricle; nAo = native aorta; nPA = native pulmonary artery; rv = right ventricle.

dominant left ventricle. For patients with concordant ventriculoarterial connections palliated only with a classical Glenn shunt, progressive diminution or closure of the VSD could effectively isolate the left pulmonary artery, a very important and serious complication.[50–52,59] Some patients have a very restrictive ovale foramen and this would limit cardiac output as well. In a rare patient the flap of the ovale foramen assumed aneurysmal proportions, herniating like a "ping-pong" ball into the left atrium and left ventricle.[71] There is ample clinical experience with balloon atrial septostomy in the patient with tricuspid atresia.[72]

Relatively little clinical information on the natural history of substantial cohorts of patients with tricuspid atresia who have received no therapy, either medical or surgical, has been published.[44–47] A rare individual with tricuspid atresia may survive many years without surgical intervention.[44–46,57] In this regard, Gerlis and his colleagues reported the case of a man who died at 60 years of age with a complex form of tricuspid atresia without any surgery.[45] But such long-term survival without surgical intervention is very uncommon. Fesslova and colleagues reported on 111 patients with tricuspid atresia seen from 1972 to 1982, most of whom had been palliated.[54] Nine per cent died during the first month; 13% within the first 3 months; and 20% during the first 6 months. Sixty-nine per cent of all deaths occurred during the first year of life. Six patients in this series died without surgery at a mean age of 32.2 ± 12.3 days. Similar results have been published by Patel and his colleagues.[48] Dick and his colleagues reported on the clinical course of 101 patients with tricuspid atresia seen at the Boston Children's Hospital from 1941, several years before the introduction of the Blalock–Taussig operation and 1973, just before the Fontan era began at their hospital.[47] Overall survival of this cohort to 15 years of age was *c*. 50% (Fig. 29-4). The overall surgical mortality in this review was 23% and this review did not include the Fontan experience. For those patients with reduced pulmonary blood flow and no surgical palliation, 90% died within the first year of life. The Prospective Bohemia Survival Study identified 39 children at birth with tricuspid atresia from the 815 569 children born between 1980 and 1990.[73] This gives a prevalence of 0.048 per 1000 live births or 0.78% of all heart malformations. Nearly 72% reached the age of 1 month; between the first and sixth month of age, the mean survival curve continued to decline to 48.72%, and at 1 year of age, the survival rate was 46.15%. The decline in the survival curve stopped at 10 years to 35.90% and remained at this level to 15 years of age.[73]

In 1989, we reported on the course of 84 infants with tricuspid atresia seen at the Toronto Hospital for Sick Children in the first year of life between 1970 and 1984 (Fig. 29-5).[55] This time period embraced the beginning of the Fontan era at our institution and the earliest clinical experience with prostaglandin administration. During this era, our Fontan mortality for tricuspid atresia was 6%, but we felt it important to examine the outcome of the entire cohort. For the entire cohort, an estimate of the probability of surviving for 1 year was 64% (95% CL, 54% to 74%) and to 8 years was 55% (95% CL, 44% to 66%). The overall surgical mortality for the palliative procedures was 35.8%, with 11 deaths in the first month of life. Of the nearly 40% of our entire cohort who died or who were excluded from the Fontan, the reasons included early death following initial palliative procedures, sudden cardiac death, or the development of subaortic stenosis, severe pulmonary artery distortion, and/or ventricular dysfunction. Over the past decade our institutional mortality for the Fontan procedure has fallen to < 3% and mortality for all forms of palliation leading to the Fontan for patients with tricuspid atresia has declined as well. Franklin and

his colleagues carried out a similar study, reviewing the survival and suitability for the Fontan procedure of 237 patients with tricuspid atresia presenting in infancy.[56] This very large clinical experience included patients seen at the London Great Ormond Street Hospital for Sick Children and the Royal Brompton within the first year of life from 1972 to 1987. Overall actuarial survival was 72% at 1 year, 53% at 5 years, and 46% at 10 years. Univariate risk-factor analysis established that discordant ventriculoarterial connections, pulmonary atresia, aortic arch obstruction, and subaortic stenosis were associated with poor survival (Fig. 29-6), virtually identical to our observations, while balanced pulmonary blood flow and older age at presentation were beneficial. In the consideration of palliative procedures, survival was worse for patients requiring banding of the pulmonary trunk with aortic arch repair. On retrospective review of 204 patients judged suitable for the Fontan at presentation, 99 (48%) are known to have died before a Fontan procedure or became unsuitable for such surgery during the follow-up.

We have recently extended our observations to 225 patients with tricuspid atresia diagnosed between 1971 and 1999 at the Toronto Hospital for Sick Children.[74] Twenty-one per cent had discordant ventriculoarterial connections; 75% of the entire cohort pulmonary outflow tract obstruction and 11% aortic outflow tract obstruction. There were a total of 72 deaths (32%), with 10 deaths before any intervention. Palliative procedures were performed in 203 patients, including 151 systemic shunts; 27 pulmonary artery banding; and 60 venous shunts; and overall 44 of these 207 patients died. 137 patients underwent a Fontan procedure with 7 early and 8 late deaths. Before Fontan, at least one procedure was performed in 90% of patients (n = 203). Forty-four deaths occurred after an initial palliation, 7 early deaths after Fontan procedure and 11 late deaths after the Fontan procedure. Total survival for the cohort was 81% at 1 year and 64% at 15 years. There were no significant changes in mortality with the Fontan procedure over the study time period. Survival following the Fontan procedure was 93%, 87% and 81% at 1, 5, and 10 years (Figs 29-7, 29-8). The Fontan procedure was performed in 137 (61%) of 225 patients. In 9 of these patients the Fontan operation was performed in a single stage, without any prior palliation. The types of connections that were

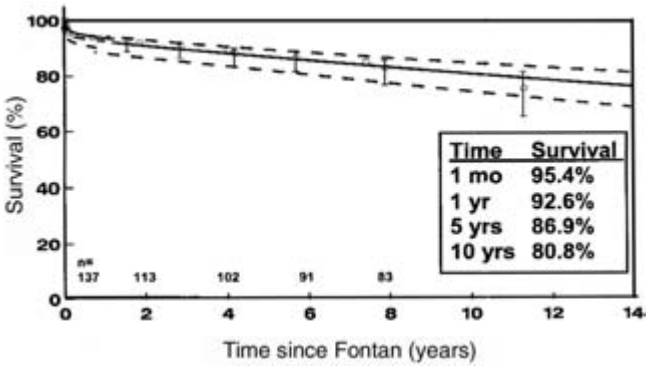

Fig. 29-8 Kaplan–Meier actuarial survival curve depicting survival from time since Fontan of Toronto cohort.

used for construction of a Fontan circuit changed over time. Early in the experience, atriopulmonary ($n = 54$, 40%) or right atrioventricular conduit ($n = 44$, 32%) connections were constructed. A lateral tunnel ($n = 24$, 18%) or extracardiac conduit ($n = 14$, 10%) connection were favored in the more recent and current eras. A fenestration was used in 33 patients (24%). With each consecutive birth cohort, the median age at which the Fontan was performed declined significantly. Reoperation or subsequent interventions were required in 53 patients (39%). Two patients after the Fontan required cardiac transplantation. This experience confirms our earlier observations and those of Franklin and colleagues;[55,56] namely that while outcomes for children with tricuspid atresia are improving, an important proportion of patients continue to die before intervention or Fontan palliation, or are not suitable candidates for the Fontan procedure. Multiple procedures and interventions are required in the majority of patients before the Fontan procedure, in order to regulate pulmonary blood flow, maintain an unrestrictive atrial communication, address systemic outflow tract outflow obstruction, rehabilitate pulmonary arterial stenoses and stage with cavopulmonary connections. Ashburn and his colleagues for the Congenital Heart Surgeons Study have studied the outcomes of 112 infants with tricuspid atresia and concordant ventriculoarterial connections seen at the participating institutions within the first 3 months of age.[56A] The mean birthweight was 3.1 kg and 15% had noncardiac anomalies. Twenty per cent had pulmonary atresia; 50% had restricted pulmonary blood flow, and 20% excessive pulmonary blood flow. An arterial shunt was performed as an initial shunt in 67%; cavopulmonary shunt as the initial shunt in 24%, and pulmonary artery banding in 9%. By the conclusion of the study, 11 patients had died, 10 before the Fontan. With a variety of strategies to reach a Fontan, current survival was estimated to be 92% and 88% at 1 and 3 years, respectively. Thus results for patients with the "ideal" form of tricuspid atresia continue to improve. Warnes and Somerville have commented on the outcomes of 17 adolescents and adults with tricuspid atresia and transposition.[75] Most of the patients in this series had either died or were disabled, and subaortic stenosis and pulmonary vascular obstructive disease contributed to morbidity and mortality. There is another group of patients with a form of tricuspid atresia who fare very poorly. This is the group with an absent pulmonary valve, imperforate tricuspid valve, and regional defective myocardial development with myocardial noncompaction.[76–82] This entity is discussed in Chapter 17 and isolated myocardial noncompaction in Chapter 41G. Suffice it to say, patients with this combination of anomalies only rarely survive to Fontan palliation.[82]

The concept by Fontan and Baudet of performing an atriopulmonary connection and atrial separation for the patient with tricuspid atresia is one of the signal contributions for patients with congenital heart disease during the last half of the 20th century (see Chapter 36).[12,83] This procedure and its many modifications has extended the quality and length of life for those patients not amenable to a biventricular repair.[84] From the earliest report of the Fontan procedure for the patient with tricuspid atresia to contemporary results, surgical results have continued to improve with a risk of perioperative death in most centers of 5% or less and predicted survival to 10–15 years of 70% or more (see Chapter 36). The Mayo Clinic reported on early and late results of a 25-year experience with the Fontan in 216 patients with tricuspid atresia.[85] The median follow-up of this cohort was 13 years and 79% of the patients survived. In the most recent decade, the operative mortality was only 2%. Eighty-nine per cent of surviving patients were in New York Heart Association class 1 or 2. The improved surgical results are predicated on a variety of issues including strict adherence to the criteria for performing this operation, perhaps staging with a bidirectional cavopulmonary shunt, better anaesthetic, intraoperative care, atrial fenestration, and care in the critical care unit postoperatively[84] (see also Chapter 36). In addition, early takedown of the failing Fontan contributed to better surgical results. The Fontan procedure, its evolution in technique and ongoing evaluation of the criteria for performing this operation are reviewed in detail in Chapter 36. But the aftermath of the Fontan may be characterized in some patients by one or more potentially life-threatening complications (see Chapter 37).

Pulmonary Atresia and Intact Ventricular Septum

First described by Hunter in 1783 and then by Peacock in 1869,[1,2] this uncommon form of congenital heart disease has intrigued many of us over the years.[3] In its simplest definition, pulmonary atresia and intact ventricular septum is a disorder characterized by complete membranous and in many patients muscular atresia of the right ventricular outlet.[1–6] The ventricular septum is intact, or nearly so. But pulmonary atresia and intact ventricular septum is a profoundly complex disorder encompassing tremendous morphologic heterogeneity (Figs 30-1, 30-2).[3–19] It is perhaps this wide diversity in structure that has both challenged and stimulated surgical and catheter-based therapies. The coronary artery abnormalities that are so important in many patients with pulmonary atresia and intact ventricular septum have evolved from pathologic curiosity to that of signal importance in surgical management and prognosis (Figs 30-3 to 30-6).[9,10,12,13,15,20–38] In this diversity, one feature also correlating with a poor outcome is a low pressure right ventricle reflecting gross tricuspid regurgitation and defective right ventricular muscularization.[9,10,12–15,39–41] And these two features, namely important abnormalities of the coronary circulation and a low pressure right ventricle are mutually exclusive.

Incidence and patterns of inheritance

Pulmonary atresia and intact ventricular septum is an uncommon form of congenitally malformed heart, accounting for only about 3% of newborns with serious congenital heart disease.[42] Data published in the report from the New England Regional Infant Cardiac Program identified 75 patients with this disorder, accounting for 3.3% of all babies encompassed by this study.[43] The more recently completed Baltimore–Washington Infant Study found the prevalence for pulmonary atresia and intact ventricular septum as 0.083 per 1000 live births.[44] The prospective Bohemia Survival Study identified 53 patients with pulmonary atresia and intact ventricular septum amongst 815 569 children born between 1980 and 1990 in Bohemia.[45] These accounted for a prevalence of 0.06 per 1000 live births and 1.05% of all heart malformations surveyed during this study. This lesion accounts for 0.71% of all patients seen with congenital heart disease at the Toronto Hospital for Sick Children.[42] As one surveys cyanotic neonates with congenital heart disease, this disorder ranks third, following transposition of the great arteries and pulmonary atresia and ventricular septal defect.[46] Data provided by the Pediatric Cardiac Care Consortium found that pulmonary atresia accounted for 2.6% of the patients surveyed.[47] They reported that in Arkansas, the prevalence/1000 live births for this malformation was 0.065, Iowa 0.085, and Minnesota 0.058. The incidence of pulmonary atresia and intact ventricular septum for the United Kingdom and Eire was 4.5/100 000 live births based on the survey of this disorder from 1991 to 1995.[48,48A] Leonard and coworkers identified from one health region in the United Kingdom 29 patients with pulmonary atresia and intact ventricular septum from a birth cohort of 601 635 live births between 1980 and 1995, for a prevalence of 0.049 per 1000 live births.[49] Important extracardiac malformations in patients with pulmonary atresia and intact ventricular septum are uncommon.[43,48] Rarely, cases of pulmonary atresia and intact ventricular septum have been noted in patients with trisomy 18 or 21.[48]

There are a few reports of familial aggregation of this disorder, but we have not identified siblings with this disorder among > 170 families with one affected child seen in our institution.[50,51] No gender or genetic disposition amongst patients with pulmonary atresia and intact ventricular septum has been firmly established, although Chitayat and his colleagues speculate that this could be a single gene disorder.[50]

Morphogenesis

Kutsche and Van Mierop suggest that pulmonary atresia with ventricular septal defect occurs earlier in cardiac morphogenesis than pulmonary atresia and intact ventricular septum.[52] Their conclusion is based on an analysis of a number of morphologic factors including the diameter of the pulmonary trunk, the morphology of the pulmonary valve, and the morphology and topography of the arterial duct. Kutsche and Van Mierop suggest that pulmonary atresia and ventricular septal defect occurs early in cardiac morphogenesis, at or shortly after partitioning of the truncoconal part of the heart, but before partitioning of the ventricular septum. Based on these morphologic variables, they suggest that pulmonary atresia and intact ventricular septum likely occurs after cardiac septation, speculating that this disorder might reflect a prenatal inflammatory disease rather than a congenital malformation. It is possible that their conclusions of the timing of the maturational arrest are correct for some forms of hearts with pulmonary atresia and intact ventricular septum, specifically those with a nearly normal-sized right ventricle and an imperforate well-formed tricommissural pulmonary valve. Indeed, there is evidence based on serial fetal echocardiographic studies that pulmonary atresia may be acquired in some patients, and these hearts tend to have better developed right ventricles. However, there are few data to support an inflammatory process as hearts with this disorder obtained from fetuses and from the immediate newborn have

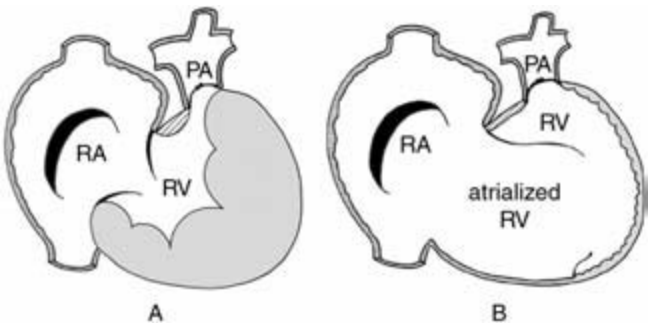

Fig. 30-1 Two forms of pulmonary atresia with intact ventricular septum. **A**. The classic form is characterized by hypoplastic and hypertensive right ventricle (RV). The tricuspid valve is small and not severely regurgitant. This form tends to be associated with ventriculocoronary arterial connections. **B**. The dilated form is associated with severe tricuspid regurgitation. Both right atrium (RA) and right ventricle are dilated. In this form, the ventriculocoronary arterial connection is not a feature. PA, pulmonary artery.

been studied histopathologically without providing any conclusive evidence of acute or subacute inflammation.[53–57] Furthermore, one would wonder whether those hearts with a diminutive right ventricle and ventriculocoronary artery connections represent an earlier insult or maturational arrest than those with a well-formed right ventricle and a well-formed though imperforate pulmonary valve. There is less certainty about the view advocated by Kutsche and Van Mierop in those patients with a tiny right ventricle and whose pulmonary valve is unicommissural and in whom there are extensive ventriculocoronary connections. Further confounding this hypothesis are those hearts with pulmonary atresia, intact ventricular septum, aortopulmonary collateral, and a right-sided aortic arch.[58–61]

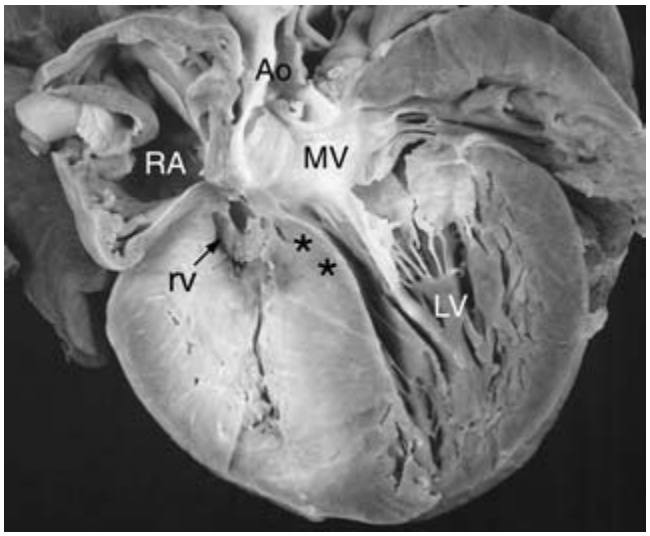

Fig. 30-2 Severely hypoplastic right ventricle (rv) in pulmonary atresia with intact ventricular septum. The right ventricular free wall and interventricular septum are very thick. The right ventricular cavity is tiny. The interventricular septum bulges into the left ventricular outflow tract (asterisk).

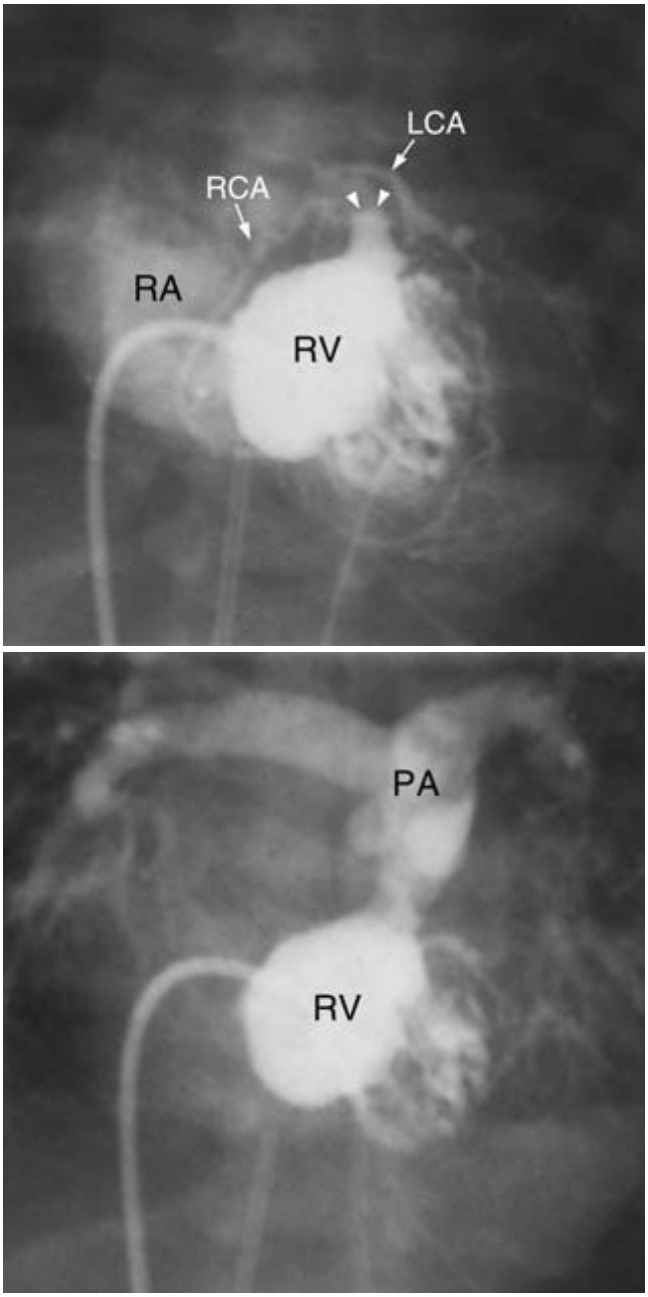

Fig. 30-3 Pulmonary atresia with intact ventricular septum. **A**. The right ventricle (RV) is moderately hypoplastic, and there is mild tricuspid regurgitation. The arrow indicates the atretic pulmonary valve. Both the right and left coronary arteries (RCA and LCA, respectively) are opacified through the ventriculocoronary connections. **B**. The patient underwent laser ablation of the atretic pulmonary valve and balloon valvuloplasty. Injection into the right ventricle after the procedure does not fill the ventriculocoronary arterial communications. PA, main pulmonary artery; RA, right atrium.

Segmental analysis

The atrial situs is normal and the atrioventricular and ventriculoarterial connections are concordant. Levocardia is present in > 98% of hearts exhibiting pulmonary atresia and intact ventricular septum. Dextrocardia with solitus atria is infrequent as

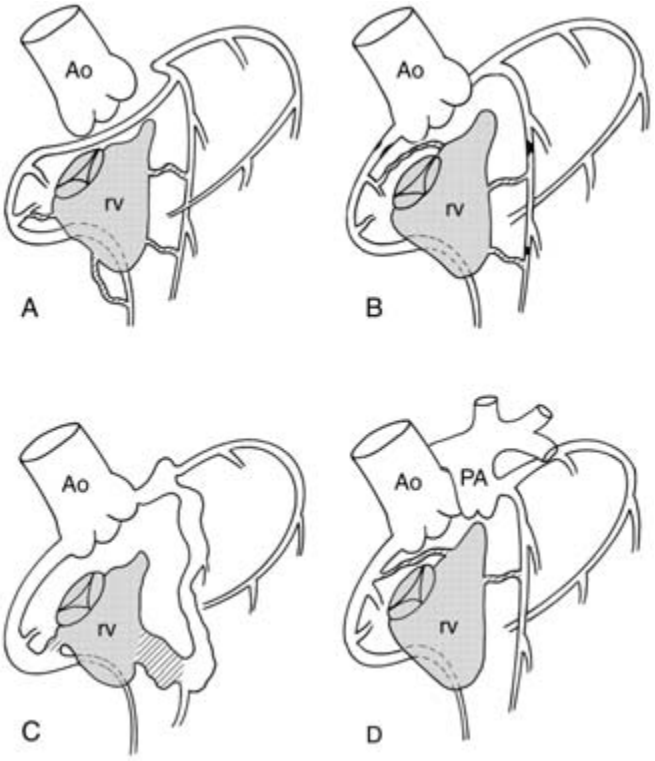

Fig. 30-4 Various forms of ventriculocoronary arterial communications causing right ventricle (RV)-dependent coronary circulation. **A**. Absent connections between the coronary arteries and aorta (Ao) with multiple ventriculocoronary connections. **B**. Proximal narrowing or interruption with multiple ventriculocoronary connections. **C**. Large fistulous communications with ectatic coronary arteries. **D**. Origin of one coronary artery from the pulmonary artery (PA) with multiple ventriculocoronary connections.

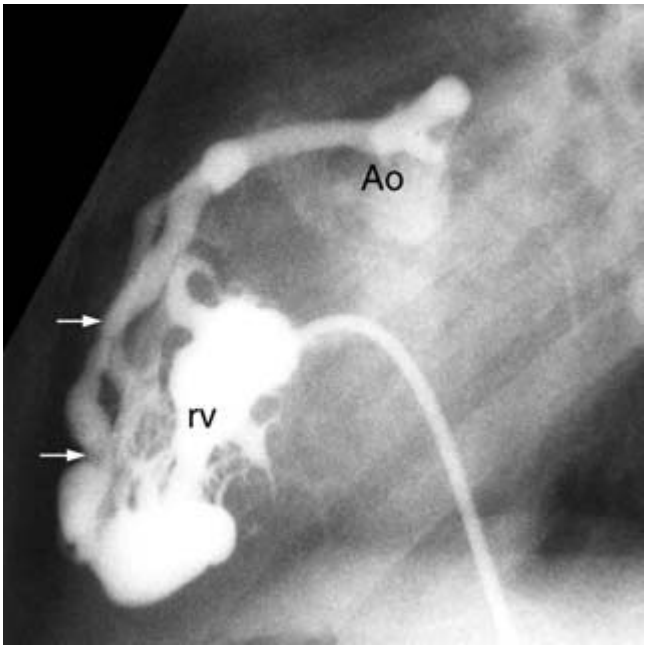

Fig. 30-5 Very large ventriculocoronary arterial communications. Right ventriculogram in lateral view shows opacification of dilated left anterior descending coronary artery (arrows) with retrograde filling of the aorta (Ao). Note the caliber changes in the left anterior descending coronary artery. The infundibular component of the right ventricle (rv) is not formed.

is pulmonary atresia and intact ventricular septum with double discordance.[3,61–65] The aortic arch is usually left-sided.

The pulmonary circulation in pulmonary atresia and intact ventricular septum

The pulmonary arteries are almost always confluent in patients with pulmonary atresia and intact ventricular septum.[3,5,48,61] The pulmonary circulation in the overwhelming majority is maintained by a left-sided patent arterial duct, although very rarely by large direct aortopulmonary collaterals.[58–61] There is usually a main pulmonary trunk with imperforate continuity with the atretic pulmonary valve. Severe underdevelopment of the branch pulmonary arteries is uncommon.[3,5] Left pulmonary artery stenosis at the site of ductal insertion has been observed in these patients.[61,66] In this regard, Marino and his colleagues suggest that the arterial duct in patients with pulmonary atresia and intact ventricular septum constricts earlier than the arterial duct in patients with pulmonary atresia and ventricular septal defect.[67] Rarely the pulmonary arteries in pulmonary atresia and intact ventricular septum are non-confluent, each supported by its arterial duct.[61,68] In one case which we reported the right pulmonary artery originated from a right-sided arterial duct, while the main pulmonary trunk and left pulmonary artery were connected to a fifth aortic arch.[69] A pulmonary sling has also been observed in the patient with pulmonary atresia and intact ventricular septum.[70] The lungs are often compressed in those babies with the largest hearts, and thus extremely severe tricuspid regurgitation.[3,10,61,71–75] Once thought to be underdeveloped in this situation, the histopathologic study of Tanaka and

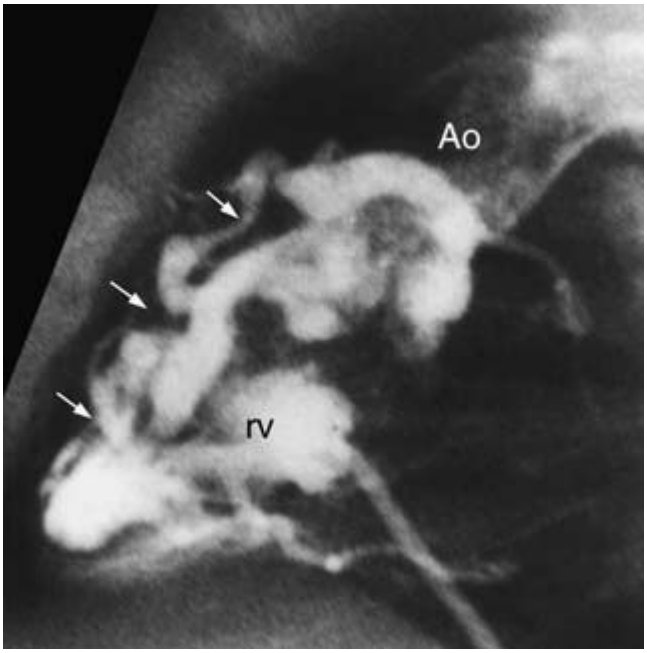

Fig. 30-6 Interruption of major coronary artery with ventriculocoronary arterial communications. Right ventriculogram in lateral view shows opacification of the left anterior descending coronary artery showing multiple levels of interruption (arrows). rv, right ventricle.

colleagues has indicated that unlike the lungs from patients with diaphragmatic hernias, lungs from neonates with massive tricuspid regurgitation and extreme cardiomegaly are not underdeveloped, nor do they demonstrate abnormal vascular extension.[75]

In the surgical and therapeutic history of this disorder, a number of anatomical considerations have been considered risk factors for poor outcome either in isolation or in combination. These include tricuspid valve size, right ventricular size, ventriculocoronary connections and a right ventricular dependent coronary circulation, amongst others.[39–41] Some have suggested that histopathological changes in the left ventricle may have an effect on long-term outcome.[76,77]

The tricuspid valve

The tricuspid valve in many patients with this disorder is severely stenotic (Fig. 30-1A), while in others the tricuspid valve is massively regurgitant (Fig. 30-1B), with a very dilated annulus, at times virtually devoid of valvular tissue.[4–11,61,78] In those patients with the most stenotic tricuspid valve, the annulus is obstructive, muscularized and all components of the valve apparatus are abnormal with a thickened free-valve margin; thickened and shortened and attenuated chordae tendineae; and abnormal papillary muscles, including a parachute configuration. The massively regurgitant tricuspid valve shows a very dilated annulus. In this situation, the tricuspid valve demonstrates features of displacement and/or dysplasia, and a portion or the entirety of the annulus may be unguarded.[8,61,71–73,78–82] Ebstein's anomaly of the tricuspid valve has been found in about 10% of autopsied patients with pulmonary atresia and intact ventricular septum.[83] Displacement without dysplasia is virtually unknown in patients with Ebstein's anomaly complicating pulmonary atresia and intact ventricular septum.[8,61,79] An obstructive form of Ebstein's valve has been observed in some patients with pulmonary atresia and intact ventricular septum.[61,84,85] The population-based study of pulmonary atresia and intact ventricular septum identified 18 patients (10%) with Ebstein's anomaly of the tricuspid valve.[48A]

A number of methodologies have been used to attempt to quantify the diameter of the tricuspid valve. Hanley and his colleagues have advocated the use of the so-called tricuspid *Z*-value as a measure of the normalized tricuspid valve diameter.[41] This is the diameter of the tricuspid valve normalized to body surface area and based on the data of Rowlatt, Rimoldi, and Lev initially published in 1963.[86] The more negative the *Z*-value of the tricuspid valve, the smaller and more obstructive the tricuspid valve. The larger the *Z*-value of the tricuspid valve, the larger the tricuspid valve diameter, and the more severe the regurgitation. These authors showed that the *Z*-value was highly correlated with right ventricular cavity size; the more negative the *Z*-value, the smaller the right ventricle. This correlation was highly significant with the presence of ventriculocoronary connections as well. More recently, Drant and colleagues have provided data supporting the observation that infundibular diameter was a better predictor of right ventricular–coronary communications than the *Z*-value of the tricuspid valve.[87] Others have used a ratio between the tricuspid and mitral valves in helping to define management pathways.[88]

The right ventricle

Numerous categorizations of the right ventricle have been made in this disorder, including attempts to capture its volume.[4–7,12–15,89–103] These classifications have evolved from a qualitative assessment of cavity size (from small to very large), to a semi-morphologic characterization of the ventricle in term of its morphologic components (inlet, apical trabecular, and outlet zones), to semi-quantitative assessment of the inlet–outlet dimensions. Others have provided a ratio between inlet-to-outlet dimensions.[91] Right ventricular volume determinations have also been attempted,[101] but whatever the methodology in these determinations, such techniques are challenged by the marked myocardial hypertrophy that attenuates the apical trabecular part and infundibulum. The right ventricle in some of these patients is very underdeveloped, seemingly formed only of an inlet portion.[7,11,61,89,90] In others, the right ventricle has an inlet and trabecular portion, while in others the right ventricle is represented by inlet, apical trabecular, and infundibular components. The degree of investment of the components in any given patient varies considerably, and muscular hypertrophy and overgrowth may obviate recognition of the trabecular and outlet portions of the right ventricle.[7,11,61] The right ventricular myocardium in those babies with the severest forms of tricuspid regurgitation may be very thinned and may transilluminate, and in others the deficiency of the myocardium may be so severe as to suggest Uhl's anomaly.[6,61] There is no doubt that with relief of outflow tract obstruction, many right ventricles demonstrate growth, stimulated in part by post-interventional pulmonary regurgitation and from remodeling with regression of hypertrophy.[91–95,100,101]

The coronary circulation

A remarkable evolution in our understanding of the coronary artery circulation in patients with pulmonary atresia and intact ventricular septum has occurred, and the disordered coronary circulation has had a profound effect on surgical management and outcome (Figs 30-3 to 30-6).[3,9,12–15,19–38] Ventriculocoronary connections and myocardial sinusoids are an important aspect of this disorder. Though these peculiar connections between the cavity of the right ventricle and the coronary arteries were observed at the autopsy table > 75 years ago,[20,103] it is just about three decades ago when Freedom and Harrington suggested that such connections might promote myocardial ischemia.[29] A substantial literature has subsequently been published defining the character of the coronary arteries, their pathology, and the coronary circulation in these patients, and surgical strategies have been defined on the basis of the coronary circulation. Gittenberger-de Groot and her colleagues have recently published a comprehensive review of the histopathology of ventriculocoronary arterial communications.[35] In the UK National Collaborative Study of pulmonary atresia and intact ventricular septum, of 140 patients identified since 1991, the coronary arteries were considered normal in 58% and minor and major coronary artery fistulae were identified in 15% and 17% respectively. Ten patients were considered to have coronary artery stenosis.[48] The median tricuspid *Z*-value for this cohort of patients was minus 1.6. Kaufman and Anderson in 1963 commented on the frequent association between hearts with ventriculocoronary connections, and pulmonary atresia and intact ventricular septum, but no specific functionality was assigned to

these peculiar communications.[104] These observations have been more recently confirmed by Schutte and her colleagues.[105] An extensive literature has documented the vast array of changes in the coronary arteries in patients with pulmonary atresia and intact ventricular septum.[3,9,12–15,19–38] The histopathologic alterations of those coronary arteries participating in the ventriculocoronary communication is not characterized by inflammation as once thought. Rather the process demonstrates myointimal hyperplasia with a rich background of glycosoaminoglycans.[3,9,12,13,15,61] There is a wide spectrum of histopathologic lesions of both the extramural and intramural coronary arteries. These lesions range from mild degrees of intimal and medial thickening in which a continuous internal elastic lamina and normal lumen is present to a loss of normal arterial wall morphology with replacement of the arterial wall by fibrocellular tissue containing irregular, non-organized elastin strands and severe stenosis or obliteration of the arterial lumen. Some have designated these changes "fibroelastosis" of the coronary arteries, but it is clear that the emphasis should be placed on myointimal hyperplasia.[27] Staining for glycosaminoglycans shows the prominence of ground substance formation by the activated smooth muscle cells, rather than reduplicated elastica and collagen that is characteristic of fibroelastosis. This pathologic process results in profound distortion of the normal architecture, eventuating in endothelial irregularity, stenosis or interruption. These coronary arterial changes occur only in patients with ventriculocoronary connections, and by inference, with a hypertensive right ventricle. We have speculated that the pathogenesis of these arterial lesions is predicated on the repeated and sustained injury to the coronary arterial intima from high-pressure right ventricular systolic turbulent blood flow mediated by the presence of the ventriculocoronary connections.[124] Intra- or extramural coronary arteries remote from the ventriculocoronary connections demonstrate less severe arterial lesions. These lesions have been found in fetal hearts with pulmonary atresia and intact ventricular septum and in hearts of the immediate newborn.[53] The abnormalities of coronary origin and distribution in patients with pulmonary atresia and intact ventricular septum embrace the same spectrum of those abnormalities as seen in patients with otherwise normal hearts, including abnormalities of origin, epicardial course, and number. A single coronary artery may originate from the aorta, or rarely from the pulmonary trunk.[106,107] There are a number of congenital and acquired conditions of the coronary circulation specific to pulmonary atresia and intact ventricular septum that impact on surgical management. These include absence of proximal aortocoronary connection between one or both coronary arteries; coronary arterial stenosis or interruption; or a so-called coronary–cameral fistula with a major fistula between right or left coronary artery and the right ventricle.[3,9,12–15,19–38,53,54,61,64,95,108–116] In the population-based study published by Daubeney and his colleagues, coronary arterial abnormalities were identified in 45.8% of 183 liveborn infants with pulmonary atresia and intact ventricular septum.[48A] Ten patients (7.6%) were considered to have a right ventricular-dependent circulation.

A right ventricular-dependent coronary artery circulation

As the characterization of the unusual coronary circulation in patients with pulmonary atresia and intact ventricular septum increased, it became evident that surgical outcomes were related to, or determined at least in part by the involvement of the coronary arteries. Clearly important to surgical management was recognition of the concept of a right ventricular-dependent coronary artery circulation and its integration into surgical algorithms (Figs 30-4 to 30-6).[3,9,12–15,19–38,53,54,61,64,95,108–116] In the normal circulation, the aortic diastolic pressure is the driving pressure for coronary blood flow. Those factors reducing aortic diastolic pressure, shortening diastole, reducing aortic compliance, etc., will compromise coronary blood flow. The presence of ventriculocoronary artery connections promotes coronary artery stenosis and interruption and aortic diastolic pressure is often insufficient to drive coronary blood flow when there are obstructive lesions within the coronary circulation. Thus in a coronary circulation that is wholly or in part right ventricular dependent, it is both the blood that gets into the right ventricle and the systemic or suprasystemic systolic right ventricular pressure that drive the coronary circulation in a retrograde fashion. Yet this process may lead to further coronary arterial distortions. The coronary circulation was considered wholly right ventricular dependent in 9% of the 145 patients enrolled in the Congenital Heart Surgeons Study.[41] These data are very similar to those published from this institution in a series of papers addressing the coronary circulation.[3,12–15,19,39,40,61] The management corollary to this is clear: interference with blood flow into the right ventricle or reduction of right ventricular systolic pressure in those situations in which the coronary circulation is right ventricular dependent could result in myocardial ischemia, infarction, and death. These observations were clearly substantiated by our own observations published by Coles and his colleagues as well as in the Congenital Heart Surgeons multi-institutional study of pulmonary atresia and intact ventricular septum.[39,41] One hundred and seventy-one neonates with pulmonary atresia and intact ventricular septum were entered into a prospective, multi-institutional study between January 1, 1987 and January 1, 1991 under the aegis of the Congenital Heart Surgeons Study.[41] Multivariable analysis of their data showed that small diameter of the tricuspid valve, a coronary circulation that was severely right ventricular dependent, birthweight, the date and type of initial surgical procedures were risk factors for time related death. The data on the deleterious effects of ventriculocoronary connections and a right ventricular-dependent coronary circulation as defined in the publication of Hanley *et al.* are similar to the data published from Toronto. Giglia and her colleagues from the Children's Hospital in Boston studying the influence of right heart size on outcome in patients with pulmonary atresia and intact ventricular septum have come to similar conclusions: "These results support our current hypothesis that coronary artery anatomy and not right ventricular or tricuspid valvar hypoplasia predicts which patients with pulmonary atresia and intact ventricular septum will do well after early right ventricular decompression."[100] While this study did not find a correlation between small right heart size and survival, the data of Giglia and her colleagues appropriately places the emphasis on the risk of right ventricular decompression on the nature of the coronary circulation. Those patients with a massive coronary artery–cameral (right ventricular) fistula are also right ventricular dependent. If the right ventricular pressure is reduced, such patients will develop a fatal steal, rapidly leading to coronary artery insufficiency, and myocardial ischemia and/or infarction.[38,61] We have reported the most unusual findings in one patient who lacked

any proximal aortocoronary connection. Unique to this patient a direct systemic artery connected the descending thoracic aorta to the left coronary system in this baby.[36]

The left ventricle

Akiba and Becker in a study of the left ventricle in patients with pulmonary atresia and intact ventricular septum found that four of eight hearts in their study showed short and almost dysplastic chords of the mitral valve, and one heart exhibited a small central cleft of the anterior mitral leaflet.[76] The left ventricle may exhibit variable degrees of hypertrophy, especially in those patients surviving past infancy. Some years ago, Zuberbuhler and Anderson called attention to a convexity of the outlet portion of the interventricular septum occurring in those patients with small and very hypertensive right ventricles.[7] We and others have also noted this convexity of the ventricular septum in patients with the hypertensive form of pulmonary atresia and intact ventricular septum (Figs 30-2, 30-7).[76,117,118] This subaortic bulge only rarely is thought to promote left ventricular outflow tract obstruction before Fontan's operation. We have observed severe left ventricular outflow tract obstruction resulting in death occurring after Fontan's operation when there is an unfavorable change in the ratio between left ventricular mass/end-diastolic volume.[118] Aortic valve stenosis has also been well described in patients with pulmonary atresia and intact ventricular septum, including the neonate with critical aortic stenosis, or the somewhat older child with severe aortic valve stenosis.[119,120]

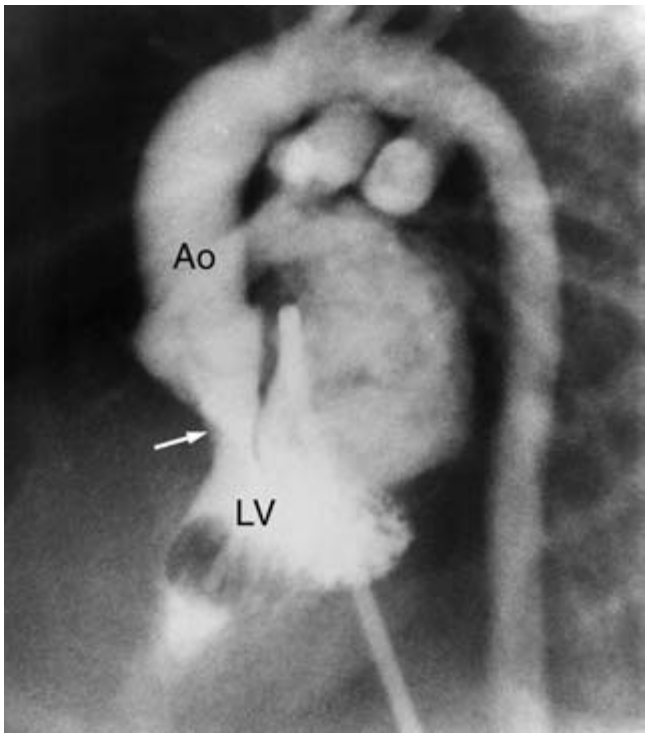

Fig. 30-7 Left ventriculogram after biventricular repair in a patient with pulmonary atresia and intact ventricular septum shows convexity (arrow) of the outlet portion of the ventricular septum. Ao, aorta; LV, left ventricle.

Myocardial abnormalities

The myocardium of patients with pulmonary atresia and intact ventricular septum demonstrates a wide range of myocardial abnormalities.[3,10,12–15,19,32,33,35,53–57,61,76,77,121–131] In view of the profound disturbances in the coronary circulation, it is not surprising that frank ischemia, fibrosis, infarction and myocardial rupture have been identified in these patients. In a provocative paper, Akiba and Becker suggest that disease of the left ventricle might be the limiting factor for long-lasting successful surgical intervention.[76] They found in the eight hearts that they studied grossly and microscopically signs of acute myocardial ischemia, and the volume density of interfiber collagen showed high levels in all, within the range of normal in five patients, but exceeding twice the standard deviation of normal in three patients. The subendocardium was disproportionately disadvantaged with higher levels of interfiber collagen than the subepicardium. They suggest that the high levels of endomysial collagen are consistent with chronic ischemia in relation to left ventricular hypertrophy, and that these abnormalities may render the left ventricle less able to cope with a volume load, and thus the left ventricle might be the limiting factor for long-lasting successful surgical intervention. Other abnormalities include myocardial disarray, the appearance of so-called spongy myocardium, and ventricular endocardial fibroelastosis. There is certainly ample clinical and morphologic evidence that the left ventricle in patients with pulmonary atresia and intact ventricular septum is abnormally hypertrophied and non-compliant. The capillary distribution in the ventricles of hearts with pulmonary atresia and intact ventricular septum has been studied by Oosthoek and colleagues.[77] Disarray and other disturbances of capillaries and myocytes were found in hearts with pulmonary atresia and intact ventricular septum, a hypoplastic right ventricle and ventriculocoronary connections. They found that these changes were more extensive when coronary artery interruptions were present.[77] The right ventricular myocardium may be particularly thinned in those babies with severe tricuspid regurgitation.

Outcome analysis

A number of studies of the prenatal recognition of pulmonary atresia and intact ventricular septum have been published, with some reports as well as fetal recognition of ventriculocoronary connections.[71–73,120,132–136] There is increasing evidence that fetuses with florid tricuspid regurgitation do not fare well.[71–73] Such fetuses are known to develop right-sided heart failure with pleural and pericardial effusions, ascites, pulmonary hypoplasia, and fetal death. Thus fetal loss might be anticipated in the specific subset of patients with pulmonary atresia, intact ventricular septum, extremely severe tricuspid regurgitation, and a low pressure right ventricle. Rarely, the fetus with a hypertensive right ventricle and a tenuous coronary artery circulation may experience progressive left ventricular dysfunction, with a fetal death. We have also seen one fetus who died because of a nearly sealed ovale foramen. Maeno and his colleagues reported in 1999 the Toronto Hospital for Sick Children's experience from 1989 to December 1997 with the prenatal recognition of right ventricular outflow tract obstruction with intact ventricular septum and also commented on the detection of ventriculocoronary connections.[135] For the purpose of this review, they excluded cases with severe tricuspid regurgitation where such

connections would not be anticipated. Of 15 fetuses with pulmonary atresia and intact ventricular septum, eight families chose to terminate the pregnancy; seven underwent some form of intervention and six of these survived. Of 13 patients assessed for ventriculocoronary communications, seven were diagnosed correctly, consistent with other recent reports on the role of fetal ultrasonography in the recognition of ventriculocoronary connections. Others have also reported their experience with prenatal recognition of coronary arterial abnormalities in this group of patients.[135A] Sharland, in her personal series of 70 cases of pulmonary atresia and intact ventricular septum with a small right ventricle detected prenatally, 58% elected to terminate the pregnancy.[134] There were a further 6 spontaneous fetal deaths, and another 6 deaths in the neonatal period. Thus this particular cohort recognized prenatally is substantially reduced by the time the neonatal period has concluded. The outlook for the group with the dilated right ventricle and gross tricuspid regurgitation was terrible. Again, from the observations of Sharland, 31 fetuses were recognized with this expression of the disorder. Eighteen families chose termination of pregnancy; there were 5 intrauterine deaths, and 8 neonatal deaths. Daubeney and his colleagues studied the impact of fetal echocardiography on incidence of pulmonary atresia and intact ventricular septum at birth and on postnatal outcome.[48] There were 86 fetal diagnoses made at a mean age of 22 weeks of gestation, leading to 53 terminations of pregnancy (61%), 4 intrauterine deaths (5%), and 29 live births (34%). The liveborn incidence of this disorder would have been 5.6 per 100 000 births in England and Wales, 5.3 in Scotland, and unchanged in Eire and Northern Ireland, if there were no termination of pregnancy and assuming no further spontaneous fetal loss. Twenty of the fetuses (23.3%) had severe tricuspid regurgitation, and in 9 of these were thought to have Ebstein's deformity of the tricuspid valve. There was no difference in outcome between the 29 liveborn cases with fetal recognition and the remaining 154 liveborn infants not diagnosed prenatally. Because the pulmonary circulation in the overwhelming majority of these patients is duct mediated, without intervention the majority will die coincident with ductal closure.[3,14,46,61] Rarely survival without intervention is documented, usually with a more stable source of pulmonary blood flow (aortopulmonary window or coronary-to-pulmonary artery fistula).[137,138]

The history of palliation of patients with pulmonary atresia and intact ventricular septum begins with the systemic-to-pulmonary arterial shunt; cavopulmonary shunt; open and closed pulmonary valvotomy; right ventricular outflow tract reconstruction with a transannular patch; right ventricular overhaul; the Fontan procedure, the one-and-a-half ventricle repair with or without ligation of the right pulmonary artery proximal to the site of the cavopulmonary anastomosis.[39,41,47,89–93,100,114,115,139–151] There is small experience with stenting of the arterial duct as a maneuver to palliate these patients.[152,153] More recently transcatheter perforation of the imperforate pulmonary valve has been accomplished with reasonable outcome in the patients so treated (Fig. 30-3).[154–157] From the 1950s to the early 1970s these babies were palliated with a variety of systemic-to-pulmonary artery shunts, including the Blalock–Taussig shunt, the Potts and Waterston shunt. The mortality for these very hypoxic babies was substantial, but some survived to benefit from a cavopulmonary shunt.[158] Open and closed pulmonary valvotomies had limited success, but some babies, particularly those with a well-formed ventricle, did well. Fortunately the medical and surgical outlook for many patients with pulmonary atresia and intact ventricular septum continues to improve. The reasons for this are complex and reflect amongst many factors the ever-improved "platform" for neonatal care. The introduction of prostanoid therapy in 1976 allowed one to stabilize these babies before any form of intervention was considered. It became clear that some babies were severely compromised and died as a result of the combination of a systemic-to-pulmonary artery surgical shunt and a patent arterial duct, and that the duct should be ligated at the time the shunt is constructed.[159] Pacileo and his colleagues have shown that in patients without ventriculocoronary connections left ventricular contractility indices are compromised after a systemic to pulmonary arterial shunt.[159A] The recognition of the disordered coronary circulation and the concept of a right ventricular dependent coronary circulation which evolved through the late 1970s and 1980s led to different surgical algorithms. Clearly while some of these patients are not candidates for a biventricular repair for a variety of reasons, univentricular palliation of the Fontan type or the one-and-a-half ventricle repair has certainly salvaged some of these children, as has cardiac transplantation. The concept of a right ventricular overhaul benefited some of these patients as well.[93] Radiofrequency or laser perforation of the imperforate pulmonary valve has also been an important development for some of these patients (Fig. 30-3). However, for the baby with very severe tricuspid regurgitation and gross cardiomegaly, the outlook is still poor despite the innovative approach of Starnes and his colleagues, and now others.[160–162] Many have published therapeutic/surgical algorithms over the years, reporting varying degrees of success in relatively small numbers of patients. Some have interposed a conduit between the right ventricle and aorta to equilibrate right ventricular and aortic pressure and to perfuse the right ventricle and the coronary arteries with oxygenated blood.[139–141]

Samanek and Voriskova have reported on the outcome of 53 patients with pulmonary atresia and intact ventricular septum identified in Bohemia born between 1980 and 1990.[45] Twenty-four and a half per cent of these died during the first week of life and by 5 years survival was only 7.55% where it remained stable to 15 years of age.[45] The outcome of children born with pulmonary atresia and intact ventricular septum in Sweden from 1980 to 1999 has just been reported.[163] A total of 84 children were born with pulmonary atresia and intact ventricular septum, giving an incidence of 4.2 per 100 000 live births. In all, 77 were operated on with a 1-year survival rate of 75%. Thirty-six children had ventriculocoronary communications, with a 1-year survival rate of 50%. At the end of the study period, 52 children were alive, 32 with biventricular repair, and 19 with univentricular repair. Follow-up time was 14 days to 20 years (median 6 years). Statistical analysis of incremental risk factors for death showed statistical significance for low birth weight, male sex, muscular pulmonary atresia, and having a systemic-to-pulmonary shunt as the sole initial intervention. For the cohort undergoing surgery, survival analysis revealed a survival rate of 81% at 1 month, 69% at 4 years, and 68% at 10 years after the initial surgery. Leonard and coworkers have provided some interesting data on the natural and unnatural history of patients with pulmonary atresia.[49] They reported the outcomes of 129 patients born with pulmonary atresia from 1980 to 1995 in the Northern Health Region of England. Twenty-nine had pulmonary atresia and an intact ventricular septum, 60 had

pulmonary atresia with a ventricular septal defect, and 40 had complex pulmonary atresia.[49] The total mortality was 72 of the 129 (56%), with 15 deaths during the first week and 49 in the first year. There were 23 surgical deaths, 33 hospital deaths not related to surgery, and 16 sudden deaths, 12 of these remaining unexplained. For the group of 29 patients with pulmonary atresia and an intact ventricular septum, 15 (52%) died in the first year. This group experienced 6 surgical deaths at a mean age of 65 days, ranging from 3 to 345 days; 7 hospital deaths at a mean age of 125 days, and there were 3 sudden deaths at a mean age of 975 days.[49]

Just as surgical algorithms continued to evolve so did clinical and imaging investigations of congenital heart patients as well. This is not the appropriate forum to discuss all those imaging modalities that have been used to investigate patients with pulmonary atresia and intact ventricular septum as there is an extensive literature devoted to this aspect.[14,61] There is compelling clinical evidence that outcome of surgical intervention is irrevocably linked to a precise assessment of the coronary circulation. This assessment is not sufficient if only the presence of ventriculocoronary connections is determined. The specific calibre of the coronary arteries, areas of stenosis or interruption, ectasia, etc., must be defined. While there is ever increasing experience with echocardiography in the recognition of ventriculocoronary connections (even in the fetus), at the present time this methodology is not precise enough to forgo cardiac catheterization with angiocardiography, including selective coronary arteriography if indicated.[164–170] One cannot be reassured by the echocardiographic appearance of a normal right ventricle that ventriculocoronary connections with a right ventricular-dependent coronary circulation is excluded as we have learned from the experience of Mair and his colleagues.[146,171]

Hanley and his colleagues presented in 1993 the observations of the Congenital Heart Surgeons Study on this disorder.[41] A total of 171 neonates with pulmonary atresia and intact ventricular septum were entered into a prospective study in 31 institutions between January 1, 1987 and January 1, 1991. Survival was 81% at 1 month after the first intervention and 64% at 4 years. The incremental risk factors for death after entry were lower birth weight, smaller dimensions of the tricuspid valve and a right ventricular-dependent coronary circulation. Eighteen per cent of the living patients had received a one-ventricle repair within 3 years and 32% a two-ventricle repair; the remainder 50% had incompletely separated pulmonary and systemic circulations. Only 8 patients in this series had gross right ventricular enlargement, and the outcome for this small group was unfavorable. Reviewing updated and additional patients enrolled in the Congenital Heart Surgeons Study in 1996 Blackstone and his colleagues asked what proportion of 346 neonates with pulmonary atresia and intact ventricular septum reach definitive repair.[172] Within 5 years of enrollment, 21% went directly or in stages to a biventricular repair; 4% to a one-and-a-half ventricle repair, and 41% died before definitive repair. In their analysis, tricuspid valve size was the most important risk factor in predicting outcome. The data from the Congenital Heart Surgeons Study has recently been extended by Ashburn and colleagues.[172A] Between 1987 and 1997, 408 neonates with pulmonary atresia and intact ventricular septum were entered into a prospective study by 33 institutions. Overall survival was 77% at 1 month, 70% at 6 months, 60% at 5 years, and 58% at 15 years. Prevalence of end states 15 years after entry were: two-ventricle repair, 33%; Fontan, 20%; one-and-a-half ventricle repair, 5%; heart transplant, 2%; death before reaching definitive repair, 38%; alive without definitive repair, 2%. As one might expect, patient-related factors discriminating among end-states primarily included adequacy of right-sided heart structures, degree of aberration of coronary circulation, low birth weight, and tricuspid valve regurgitation. There was improvement in overall survival across the study period. Holding other factors constant, predicted 5-year overall survival for neonates enrolled in 1987, 1992, and 1997 was 49%, 63%, and 79%, respectively. The coronary artery anatomy in this cohort is interesting. Right ventricle-to-coronary artery fistulae were present in 126 patients (31%). Right ventricle-dependent coronary circulation, defined as supply of a major portion of left ventricle from the right ventricle through the fistulae, was present in 19 (5%) neonates. These observations are interesting considering that in 20% of the patients the end-point was the Fontan operation.

The Pediatric Cardiac Care Consortium provided outcome data on 462 operations carried out in 365 patients with pulmonary atresia and intact ventricular septum.[47] There were 60 deaths (25.6%) among 234 operations carried out in the first year of life, and 13 deaths (5.8%) for 225 operations performed in patients between 1 and 21 years of age. Of 51 Fontan procedures carried out by members of the consortium, 10 patients (19.6%) died. In this regard, Mair reported on the results of the Fontan operation in 40 patients with pulmonary atresia and intact ventricular septum.[146,171] Three early and three late deaths were encountered. In only 5 patients were ventriculocoronary connections observed, and no patient in this series had a right ventricular-dependent coronary circulation. In 1997, we reported on the outcome of 22 patients with pulmonary atresia and intact ventricular septum who had undergone a Fontan at the Toronto Hospital for Sick Children between 1980 and 1994.[147] Ventriculocoronary connections were identified in 15 of these and the coronary circulation was considered right ventricular-dependent in 5. There were 3 early and 1 late deaths. The actuarial survival at 10 years after the Fontan was 80%. There is relatively little information on the outcome of patients with pulmonary atresia, an intact ventricular septum and a right ventricular-dependent coronary circulation. Powell and his colleagues reported on 12 patients with a right ventricular-dependent coronary circulation in 2000.[173] Of 49 patients with pulmonary atresia, an intact ventricular septum diagnosed since 1986, 12 had a right ventricular-dependent coronary circulation. All underwent a modified Blalock–Taussig shunt with 1 intraoperative and 1 late sudden death. Eight patients went on to a bidirectional cavopulmonary shunt, and of these 5 have undergone a fenestrated Fontan and 3 are awaiting a fenestrated Fontan. The 5-year actuarial survival rate for this small cohort of patients was 83%. Rychik and his colleagues reviewed the surgical experience of 67 patients with pulmonary atresia and intact ventricular septum operated on at the Children's Hospital of Philadelphia between 1981 and 1998.[174] These patients were divided into three groups on the basis of the initial surgical strategy: group 1, aortopulmonary shunt alone in 31 patients; group 2, right ventricular recruitment in 32; group 3, cardiac transplant in 4. Overall actuarial survivals at 1, 5, and 8 years were 82%, 76%, and 76%, respectively. As one would anticipate, death was highest in infancy, 10 of 16, but the outcome was equivalent for all three strategies. Only one-third had a successful biventricular repair, and the tricuspid valve *Z*-score was

significantly higher in this group when compared to those who had the Fontan operation.

Fyler in 1992 showed that surgical results for pulmonary atresia and intact ventricular septum operated on at the Boston Children's Hospital had continued to improve over time.[175] More recently, Jahangiri and his colleagues also from Boston Children's Hospital extended these observations, reporting on the outcome of 47 patients who underwent surgery between January 1991 and September 1998.[176] Sixteen of these patients (34%) had a right ventricular-dependent coronary circulation, and all of these underwent a modified Blalock–Taussig shunt with one death. Fourteen of 16 patients underwent a bidirectional cavopulmonary shunt at a median of 9 months after their first operation, and nine of these had a subsequent Fontan operation without any mortality. In the 31 patients without a right ventricular-dependent coronary circulation, 6 patients underwent only a systemic-to-pulmonary artery shunt, 23 had a shunt and right ventricular decompression, and 2 had only a transannular patch. In this group of 31 patients, 10 patients had a biventricular repair, 6 a one-and-a-half ventricle repair, and 8 patients a Fontan operation, with only 1 death. The overall survival was 98% at 1 year, 5 years, and 7 years. McCrindle in a commentary on this paper does not dispute the excellence of these results, but urges some caution in the interpretation of these results as some patients were probably excluded.[177] Recently Laks and Plunkett reviewed the surgical experience with disorder at the University Of Calfornia in Los Angeles (UCLA).[178] Between 1982 and 1997, 111 patients with pulmonary atresia and intact ventricular septum underwent surgery at UCLA. They excluded 6 patients with Ebstein's anomaly of the tricuspid valve and pulmonary atresia and intact ventricular septum. A total of 63 patients with pulmonary atresia and intact ventricular septum underwent palliative procedures as neonates. Of these 20 patients had severe right ventricular hypoplasia and/or severe coronary abnormalities with a right ventricular-dependent coronary circulation. There were three early deaths in this group. The remaining 43 patients had mild to moderate right ventricular hypoplasia without a major abnormality in the coronary circulation. All of these underwent procedures to open the right ventricular outflow tract with or without a shunt. Three early and 2 late deaths occurred in this group. Early survival in this group was 90% and late survival 87%. A total of 80 patients surviving palliative procedures from UCLA and referring institutions underwent further interventions at UCLA. Of these, 19 underwent a one-and-a-half ventricle repair with a bidirectional cavopulmonary shunt, with 3 deaths. Twenty-two patients underwent a Fontan operation as later intervention, with 2 early and 1 late death. Actuarial survival for this entire group was 96% at 1 year, 89% at 5 years, and 83% at 10 years.[178] These results are excellent, acknowledging that the fate and well-being of the entire cohort was not presented.

The group in Toronto has had a long interest in pulmonary atresia and intact ventricular septum. We have focused attention on the striking morphological heterogeneity of this disorder, defined the pathologic and clinical findings of the disordered coronary circulation and those types of coronary circulation contributing to a right ventricular-dependent coronary circulation (Fig. 30-4), and have reported on the results of selective coronary arteriography in these patients. Those important changes in the myocardium and the nature of the occlusive coronary pathology have been extensively described as well. A number of papers have emanated from the Toronto Hospital for Sick Children providing our surgical experience with pulmonary atresia and intact ventricular septum. Shams and his colleagues reported on the outcome of 50 patients with pulmonary atresia and intact ventricular septum seen between 1950 and 1967.[158] The overall experience was very poor, with most of the patients dying without surgery, or in the immediate postoperative period. The majority of the patients in this series had a direct attack on the pulmonary valve or/or infundibulum and all died. The survival was considerably better for those who underwent a systemic-to-pulmonary artery shunt ± balloon septostomy as reported by Aziz and his colleagues in 1975 who documented the outcome of this approach for 15 neonates with pulmonary atresia and intact ventricular septum from 1950 to 1972.[179] The mortality in this era (just before the introduction of prostanoid therapy) for this approach was 27%. Coles and our colleagues reported in 1989 on the long-term results in neonates with pulmonary atresia and intact ventricular septum seen from 1965 through 1987.[39] This experience included 115 patients, 16 of whom died before surgical intervention. Fifty-six per cent of the patients undergoing surgery had ventriculocoronary connections. The early surgical mortality was 27.2% and the actuarial survival was only 24.7 ± 6% at 13 years postoperatively. Multivariate analysis indicated the presence of a right ventricular-dependent coronary circulation, a decreasing ratio between right ventricular and left ventricular pressure at the initial catheterization and lower weight at operation were incremental risk factors for a postoperative death. Ebstein's anomaly of the tricuspid valve was also an additional risk factor for early death. The presence of a right ventricular-dependent coronary circulation was uniformly fatal for those patients undergoing any form of right ventricular decompression or thromboexclusion of the right ventricle, but it required a number of years for this concept to mature and to be integrated into clinical practice.

We have just reviewed again our clinical experience with 210 consecutive patients with pulmonary atresia and intact ventricular septum (102 males (49%) and 108 females) seen from 1965 to 1998 at the Toronto Hospital for Sick Children.[180] Overall survival was 72% at age 1 month, 57% at 1 year, 48% at 5 years and 43% at 10 years (Fig. 30-8). Survival improved with subsequent birth cohorts ($P < 0.001$), with overall survival for 1992–98 85% at age 1 month, 75% at 1 year and 67% at 5 years (Fig. 30-9). Only earlier date of birth and the presence of Ebstein's malformation and prematurity were significant independent factors associated with decreased overall survival. After controlling for

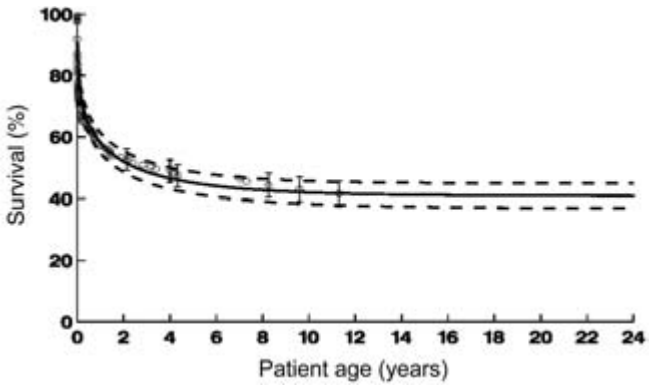

Fig. 30-8 Kaplan–Meier estimate of survival of entire cohort of patients with pulmonary atresia and intact ventricular septum.

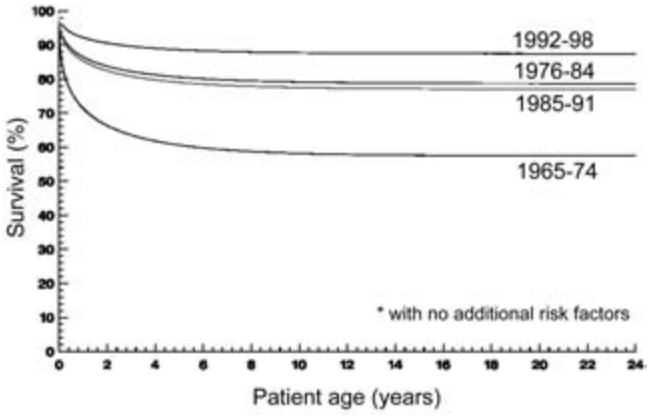

Fig. 30-9 Kaplan–Meier estimates of survival of patients with pulmonary atresia and intact ventricular septum by era. Note the improvement in the more recent time period.

these 2 factors, no other factors significantly impacted survival. Right ventricular sinusoids ($n = 182$) were present in 125 (69%) and absent in 57 (31%). Ventriculocoronary connections ($n = 180$) were present in 100 (55%) and absent in 80 (45%). These connections ($n = 95$) was confined to the left coronary artery in 13 (14%) and to right coronary artery in 5 (5%) and both to left and right coronary arteries in 77 (81%) of patients. Detailed analysis of coronary arteries was possible in 172 patients. We found normal coronary arteries in 118 (69%), proximal coronary arterial stenoses only in 20 (12%), coronary arterial dilation in 4 (2%) and proximal coronary interruption in 29 (17%). A total of 39 (23%) patients were considered to have a right ventricular-dependent coronary circulation. This experience shows how one's understanding of the disordered coronary circulation can effectively neutralize this as a risk factor for poor outcome. Those patients with a low right ventricle to left ventricle pressure ratio and Ebstein's anomaly of the tricuspid valve continued to have a poor outcome and patients with severe tricuspid regurgitation accounted for 17% of the entire cohort. Predicted actuarial survival for any era would be enhanced if these had been excluded from analysis.

Humpl and his colleagues at the Toronto Hospital for Sick Children have examined our experience in 30 patients with percutaneous balloon pulmonary valvotomy for pulmonary atresia and intact ventricular septum (Fig. 30-3).[181] From April 1992 to August 2000, 50 neonates were diagnosed with pulmonary atresia and intact ventricular septum. Of this group, 30 underwent attempted percutaneous radiofrequency-assisted pulmonary valvotomy and balloon dilatation of the pulmonary valve. The remaining 20 patients were surgically treated on the algorithm of univentricular palliation either because of an absent infundibulum,[7] a right ventricular-dependent coronary circulation,[13] or both. The median age of catheter-based intervention was 2 days, with a median weight of 3.28 kg. Perforation was successful in 27 patients. Fourteen of these eventually required a modified Blalock–Taussig shunt between 2 and 24 days after balloon dilatation. There were 3 early and 2 late deaths. At a follow-up time of 1 to 87 months, 16 patients have a biventricular circulation, 3 a one-and-a-half ventricle circulation, and 1 patient a Fontan circulation. Four patients are awaiting further palliation (current status: modified Blalock–Taussig shunt, $n = 1$ or biventricular cavopulmonary shunt $n = 3$).[182] There was no significant change of the tricuspid valve Z-score or right ventricular length Z-score with time. Agnoletti and her colleagues reported the long-term follow-up of perforation of 33 patients with pulmonary atresia and intact ventricular septum.[183] The median age and weight of these patients were 3 days and 3 kg. Of the 33 patients, 17 required neonatal surgery. At a median follow-up of 5.5 years, survival was 85% and freedom from surgery was 35%. Five patients required a partial cavopulmonary connection.[183]

The myocardium of the patient with pulmonary atresia and intact ventricular septum is thought to be intrinsically abnormal, and it is conceivable that progressive left ventricular dysfunction may become evident during continued long-term follow-up.[76,77] For those patients undergoing single ventricle palliation because of a right ventricular-dependent coronary circulation, the form and function of the coronary circulation is of course of great concern. Despite the fact that pulmonary venous blood enters the coronary circulation during right ventricular systole, the coronary vascular bed is exposed to very abnormal shear forces and turbulent flow, both of which may promote endothelial damage, contributing to coronary insufficiency. We have found that patients with ventriculocoronary connections and coronary abnormalities have a higher incidence of wall motion abnormalities than those without these findings.[130] We speculated that these wall motion abnormalities reflect ongoing myocardial ischemia and furthermore that such patients are at risk for late, sudden death. There is little information on resting or exercise myocardial perfusion studies in these patients and because of the peculiar coronary circulation, one would have to be most careful in the interpretation of the results. Sudden death has been reported in patients with pulmonary atresia and intact ventricular septum,[49] and this has been attributed to an ischemic myocardium. Furthermore, in the same group of patients there is always the substrate for a dynamic form of left ventricular outflow tract obstruction because of the potential for the interventricular septum to bulge into the left ventricular outflow tract (Figs 30-2, 30-7).[7,118] One would be concerned about the functionality of the septal perforators in this setting, again as a substrate for myocardial ischemia. These patients require very careful long-term surveillance, with particular attention to detecting important ventricular rhythm disturbances and for left ventricular dysfunction. One must be careful or cautious in the use of afterload reducing agents because of the reality of dynamic left ventricular outflow tract obstruction. There might be a role in selected cases for the judicious use of cardiospecific beta blockers.

In summary. the outcomes for patients with pulmonary atresia and intact ventricular septum continue to improve, although the surgical management of those patients with a low right ventricle/left ventricle pressure ratio continues to be difficult. The follow-up issues for these patients are also complex, depending on the underlying morphological substrate and type of repair. Those undergoing a Fontan-type of univentricular palliation are potential hosts to a wide range of complications (see Chapter 37). For those undergoing a surgical biventricular repair or one based on catheter therapy, long-term issues will likely be related to the form and function of the right ventricle, impact of chronic pulmonary regurgitation on the right ventricle and secondarily on the form and function of the tricuspid valve, and on the functional integrity of the tricuspid valve itself. Many of the same issues are germane to the patient undergoing a one-and-a-half ventricle repair.[181] In this group, attention must be paid to the form and function of the bidirectional cavopulmonary connection, remembering that aneurysmal changes have been

described in those with forward pulsatile pulmonary blood flow (see Chapter 35). The patient palliated only with a systemic-to-pulmonary artery anastomosis will likely demonstrate progressive hypoxemia as the shunt is outgrown, but chronic volume loading and a disordered coronary circulation may lead to a functional deterioration in left ventricular contractility. Some patients will evolve from a systemic-to-arterial shunt to a bidirectional cavopulmonary shunt. In those patients who do not become Fontan candidates, the development of pulmonary arteriovenous fistulae or venous collateralization may result in progressive hypoxemia and clinical deterioration (see Chapter 35).

In summary:

- Pulmonary atresia and intact ventricular septum is a disorder with profound heterogeneity.
- Termination of pregnancy and spontaneous fetal loss (especially in those with severe tricuspid regurgitation) will continue to reduce liveborn prevalence.
- Numerous catheter-based and surgical algorithms are necessary to establish either a biventricular repair, one-and-a-half ventricle repair, or univentricular palliation.
- Laser-assisted perforation of the right ventricular outflow tract with subsequent balloon dilatation has proven in some modest-sized series to provide excellent short- and medium-term results.
- Patients with a right ventricular-dependent coronary circulation have been treated successfully with univentricular palliation. The long-term effect of the disordered coronary circulation on left ventricular function is to be determined. Whether such patients are especially at risk for coronary-mediated sudden cardiac death is unclear. But the issue is worrisome.
- Some patients with particularly egregious coronary artery abnormalities are best treated with transplantation.
- Outcomes of patients with pulmonary atresia and Ebstein's anomaly of the tricuspid valve with florid cardiomegaly continue to be poor despite some limited success with conversion to tricuspid atresia, and plication of the gigantic right atrium, etc.[160–162]
- Overall, with the exception of the pulmonary atresia/Ebstein group, outcomes continue to improve.

Hypoplastic Left Heart Syndrome

While some have considered aortic atresia "the worst heart disease,"[1] the accomplishments of many over the past one-quarter century have proved this incorrect. Keith and his colleagues attribute to Dilg in 1883 and Martens in 1890 some of the earliest reports of aortic atresia, although there was an even earlier report.[1A] However real progress began just over 50 years ago when the late Dr Maurice Lev (1908–94) characterized hearts with so-called hypoplasia of the aortic tract complex (Fig. 31-1). These hearts shared in common normal situs and connections, but the left heart demonstrated varying degrees of underdevelopment.[2] Many others have subsequently studied these hearts which are united by:[3–16]

- aortic stenosis or atresia
- mitral stenosis or atresia
- varying degrees of left ventricular hypoplasia
- a patent ovale foramen or less commonly an intact atrial septum
- patent arterial duct
- hypoplasia of ascending aorta
- left ventricular endocardial sclerosis.

The right heart and main pulmonary trunk are dilated and hypertrophied and the arterial duct is the tenuous conduit to the systemic and coronary circulation. The designation "hypoplastic left heart syndrome" for this constellation of anomalies was first used by Noonan and Nadas who described the clinical profile of these patients.[17] Survival for even a short time in these patients was dependent on patency of the arterial duct and on the caliber and patency of the ovale foramen.[17,18] The "programmed" closure of the arterial duct leads invariably to death, usually within the first hours or days after birth.[17–19] Those with a very restrictive interatrial communication, or an intact atrial septum usually die within hours of birth, often with pulmonary lymphangiectasia.[20–33]

Incidence and etiology

The New England Regional Infant Cardiac Program gave a prevalence of 0.164/1000 live births for the hypoplastic left heart syndrome,[34] while the Baltimore–Washington Infant Study provided a somewhat higher prevalence of 0.267/1000 live births,[35] similar to that reported by Francannet *et al.* and their coworkers[35A,35B,35C] The prevalence for left-sided obstructive lesions obtained from the Alberta Heritage Pediatric Cardiology Program was 0.677/1000 live births, but it is unclear from their data whether this category includes lesions less severe than "hypoplastic left heart syndrome."[36] The prevalence of the hypoplastic left heart syndrome in Oregon from 1971 to 1986 was 0.162 per 1000 live births. Of the affected children in the Oregon study, 15% ± 4% died on the first day of life; 70% ± 5% within the first week; and 91% ± 3% died within 30 days.[37] Data from the prospective Bohemia Survival Study identified 172 patients with the hypoplastic left heart syndrome from 815 569 children born from 1980 to 1990.[38] This gives a prevalence of 0.21 per 1000 live births and these accounted for 3.42% of all congenital heart malformations encountered in this study.[38] This constellation of cardiac anomalies is the most common cardiac cause of congestive heart failure in the first week of life.[6,17,18]

There are several lines of evidence summarized by Grossfeld that support a genetic cause of the hypoplastic left heart syndrome.[39] The hypoplastic left heart syndrome has been recorded in siblings, and both autosomal recessive inheritance and multifactorial inheritance have been implicated.[39–55] Holmes and colleagues found a recurrence risk in siblings of 0.5% for hypoplastic left heart syndrome and 2.2% for all cardiac malformations.[47] Brenner and his colleagues found that amongst probands with one affected sibling with the hypoplastic left heart syndrome, there is a predilection for bicuspid aortic valves in first degree relatives.[48] The inference from this observation is that genetic factors likely contribute to the cause of left-heart blood-flow lesions. In addition to familial occurrences, a number of chromosomal abnormalities have been identified in patients with the hypoplastic left heart syndrome, perhaps the most common being Turner's syndrome.[45,51,54,55] Anderson more than a quarter of a century ago discussed congenital heart malformations among 109 sets of twins and triplets.[55A]

The New England Regional Infant Cardiac Program characterized babies with the hypoplastic left heart syndrome as usually full-term, of normal birth weight and for the most part free of important extracardiac malformations.[34] These observations were part of the impetus to define palliative intervention for these patients. As stated earlier, recent data are concerning, indicating that some of these patients do have chromosomal abnormalities including among others Turner's syndrome.[55,56] In addition the central nervous system of these babies has been scrutinized since increasing numbers of infants with the hypoplastic left heart syndrome are now surviving univentricular palliation. Concerning information about congenital brain anomalies associated with the hypoplastic left heart syndrome has been published by Glauser and colleagues, from the institution where Norwood and his colleagues have achieved so much with this group of patients.[57,58] Of 41 infants with the hypoplastic left heart syndrome dying in this institution from 1980 to 1985, 29% had either a major or minor central nervous system abnormality, including 3 cases of agenesis of the corpus

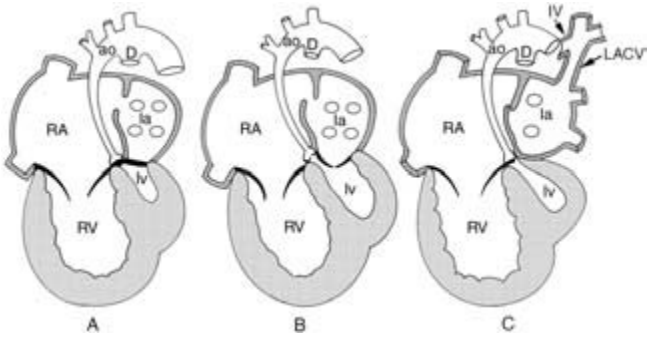

Fig. 31-1 Various forms of hypoplastic left heart syndrome. The connection between the left atrium (LA) and left ventricle (LV) can be through an atretic (**A**) or stenotic (**B**) mitral valve, or the connection can be absent (**C**). The aortic valve is atretic or critically stenotic. The ascending aorta (Ao) shows variable degree of hypoplasia and shows retrograde filling in most cases. The patent ductus arteriosus (D) is essential for survival. Interatrial communication is also essential but often restrictive and rarely absent. The left atrium (LA) can be decompressed through a levoatriocardinal vein (LACV) as in C. IV, innominate vein RA, right atrium; RV, right ventricle.

callosum, 1 case of prosencephaly. Micrencephaly was recorded in 27% of patients and a thin cortical mantle in 21%. These findings were differentiated from those acquired neuropathological changes in this group of patients.[58] The neurodevelopmental outcome of 11 patients who underwent the first stage of Norwood's palliation showed 7 had major difficulties, perhaps in retrospect reflecting some aspect of surgical technique.[59] Mutations in the cardiac homeobox gene NKX2-5 are an infrequent cause of sporadic cases of hypoplastic left heart syndrome.[59A]

Outcome analysis: evolution in diagnosis and treatment

In the era before routine application of echocardiographic imaging, and before pharmacological manipulation of the arterial duct, the majority of these babies presented in a moribund state and either without a pulse, or with diffusely weak arterial pulses.[6,14,17,18,30] There was relentless metabolic acidosis, and death quickly ensued. For those who seemed somewhat more stable or those who responded even transiently to resuscitation, a limited cardiac catheterization with angiography confirmed the diagnosis. All-too-often, passage of the catheter through the arterial duct resulted in a profound bradycardia that degenerated into a terminal ventricular dysrhythmia.[18,60–63] The application of m-mode echocardiography in the mid 1970s and then cross-sectional echocardiographic imaging of the 1980s virtually replaced the invasive methodologies to establish this diagnosis in typical cases.[18,30]

The diagnosis of the hypoplastic left heart syndrome in the 1950s and 1960s carried a uniformly fatal prognosis. Rarely, a patient with aortic atresia would survive a few years or even into the third decade of life without surgical intervention,[63–68] but the majority of babies with the hypoplastic left heart syndrome died within the first days or few weeks of life.[18,19,30] Some attempts to palliate these babies were made in this era and such palliation took the form of bilateral banding of the branch pulmonary arteries with interposition of a tube graft between the main pulmonary trunk and the descending aorta.[69–72] A few patients survived these heroic attempts, but most centers offered only compassionate care.

Several events in the contemporary history of congenital heart disease were important in providing the impetus to consider a staged approach to surgical palliation. The reality of the Fontan operation for patients with one ventricle hearts published in 1971; the ability to pharmacologically promote and maintain ductal patency by the administration of an E-type prostaglandin and thus stabilize the baby with a duct-dependent systemic circulation and the New England Regional Infant Cardiac Program that described patients with the hypoplastic left heart syndrome in a positive way all gave emphasis to a staged surgical initiative.[34,73,74] Stimulated by a surgical interest in this disorder hearts with varying degrees of left heart hypoplasia and thus potential candidates for univentricular palliation were re-examined and the many common and less common associated cardiac anomalies were fully catalogued (see Table 31-1). New knowledge emerged and older information reviewed about the anatomy of the hypoplastic left heart syndrome. This included information about coarctation of the aorta, initially considered uncommon in the hypoplastic left heart syndrome, but very common on re-examination, and its form.[75–77] The anatomy of the Eustachian valve (hypoplastic and malaligned),[78,79] tricuspid valve,[80] patterns of anomalous pulmonary venous connection,[81] alternate pathways to pulmonary venous return in the setting of premature closure of the ovale foramen, and the status of the atrial septum were all examined in detail.[82–85] Those uncommon cardiac anomalies seen in association with aortic atresia were also catalogued, including aorto-left ventricular tunnel;[86–88] atrioventricular septal defect,[71,89,90] right and left atrial isomerism,[91–95] bilateral arterial ducts, right aortic arch;[96,97] aortopulmonary window;[98,99] aortic arch interruption;[98–104] fifth aortic arch;[102–104] abnormal coronary artery origin (single, one or both),[105–107] scimitar syndrome,[108] hearts with double discordance;[109–114] univentricular hearts, absent aortic valve leaflets with left heart hypoplasia, etc.[62,97,115–121]

Throughout the mid-to-late 1970s and early 1980s, there was considerable interest in the peculiar coronary circulation often seen in the patient with pulmonary atresia and intact ventricular septum (see Chapter 30). In this setting those conditions that jeopardized normal coronary dynamics and surgical outcome were studied in detail and a number of abnormalities were described including those contributing to a right ventricular-dependent coronary circulation. Hearts with left-sided hypoplasia were then examined for similar abnormalities of the coronary circulation and evidence of coronary microvascular pathology. A similar expression of abnormalities was seen, but were invariably less severe than in those patients with right

heart obstruction.[122–129] Ventriculocoronary connections were seen primarily in those patients with a perforate mitral valve, and were rarely observed in specimens with aortic and mitral atresia.[122,124–126] Clearly one could explain this difference by the reciprocal relationship between the presence of coronary artery pathology and ventricular endocardial sclerosis.[128] But what is fascinating is why is the dense, "sugar-coating" type of ventricular endocardial sclerosis is so uncommon in patients with pulmonary atresia and intact ventricular septum and yet so prevalent in those patients with aortic atresia and a perforate mitral valve?[124] Is this related to the "color" or level of oxygenation of blood entering the ventricle and elastin synthesis? The myocardium of patients with the hypoplastic left heart syndrome was also studied, and varying degrees of myocardial disarray, ischemia and frank fibrosis with dystrophic calcification was found.[122–128]

It was William Norwood, initially at the Children's Hospital in Boston and later at the Children's Hospital of Philadelphia, who pioneered the staged approach to the palliation of babies with the hypoplastic left heart syndrome (Fig. 31-2).[130,131] Acknowledging his contributions, the designation "Norwood operation" is now firmly entrenched in our literature. The basic tenants to the initial operation as advocated and performed by Norwood included:

- provide unobstructed systemic blood flow
- provide a stable and controlled source of pulmonary blood flow
- provide a widely open atrial septum.

The operation has undergone multiple modifications from that pioneered by Norwood. Basically, the small ascending is opened and the pulmonary trunk divided. The main pulmonary artery is anastomosed and augmented by homograft tissue to the ascending aorta and the anastomosis extended distally enough to treat any aortic coarctation. Any ductal tissue that could lead to a recurrent coarctation is excised. Most now perform a modified Blalock–Taussig shunt from the base of the innominate artery or right subclavian artery to the right pulmonary artery. The pulmonary artery confluence is now routinely patched to prevent late pulmonary arterial stenosis.[132,133] Because of lack of growth of homograft material, distortion and lack of availability, Brawn and his colleagues modified the repair of the aortic arch as follows: all duct tissue is excised and the descending aorta is anastomosed to the aortic arch, which is opened back into the ascending aorta.[134] Then to this confluence is anastomosed the proximal main pulmonary artery. In some patients continuity of the aortic arch was maintained and the repair was performed with a Damus–Kaye–Stansel anastomosis. The size of the systemic-to-pulmonary shunt has also evolved over time, with most surgeons having abandoned the 4.0 mm graft, preferring to use either a 3.5 or 3.0 mm graft. From clinical trial and error, the judicious management of these patients required careful balancing of the systemic and pulmonary blood flow. Too large a shunt and hence pulmonary blood flow promoted a coronary steal, jeopardizing the myocardium and this all-too-often resulted in death.[132,135–139] Some cardiologists felt that from postoperative blood gas analysis excessive pulmonary blood flow was not implicated as a cause of death, but in nonsurvivors, low cardiac output and hypoxemia were assumed to be the major culprits.[139] A smaller systemic-to-pulmonary artery anastomosis allowed easier management of this aspect of care, acknowledging that with a smaller shunt, many of these babies would be quite hypoxic in the immediate post-operative period. Some using the larger shunt attempted to control pulmonary blood flow by ventilating the patient in a hypoxic gas mixture.[140] More recently, pulmonary venous desaturation early after Norwood palliation has been found to contribute to the degree of hypoxemia.[141] Others have shown that an anaerobic threshold was reached when the systemic venous saturation fell below 30%, and that clinical management to maintain superior caval saturation above this threshold yielded low first-stage Norwood mortality.[142] An adjustable tourniquet to manipulate pulmonary blood flow after the Norwood operation has been advocated.[143] Many factors, both physiologic as well as anatomic, obviously contribute to the level of systemic oxygenation at first stage Norwood palliation, among these the status of the pulmonary vascular bed as well as the status of the atrial septum.[30,31,33,144–149] It became clear from many clinical experiences that excessive pulmonary blood flow usually from too large a shunt increases ventricular volume work in the face of inadequate systemic cardiac output, low aortic diastolic blood pressure, and inadequate coronary perfusion, this cascade resulting all-too-frequently in death. Some have advocated the use of a small saphenous vein homograft as a superior conduit for the systemic arterial shunt in the Norwood procedure, finding this graft limits flow without the risk of thrombosis.[149A]

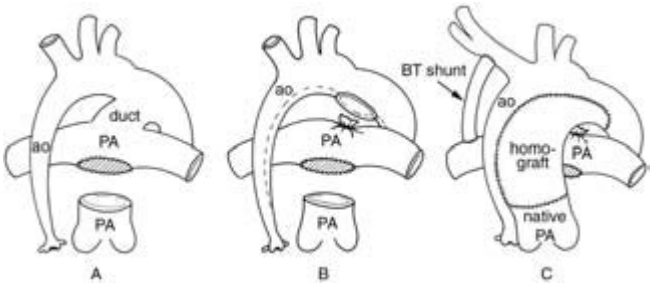

Fig. 31-2 Norwood operation. **A**. The main pulmonary artery (PA) is divided and the floor of the confluent pulmonary artery is closed with a patch or by direct suture. **B**. The ductus arteriosus is divided and completely excised, and its pulmonary arterial side is closed. The aortic incision is extended along the ventral side of the aortic arch and adjacent ascending (Ao) and descending aorta. **C**. The pulmonary artery is anastomosed to the incised aorta either directly or by using a homograft patch. A modified Blalock–Taussig (BT) shunt is placed on the right side.

Patients with severe pulmonary valve stenosis, severe congenital tricuspid regurgitation (organic, not functional), and unilateral hypoplasia of a pulmonary artery were usually deemed not candidates for staged single ventricle palliation.[150–152]

In the first years after Norwood and his colleagues initiated the staged surgical approach, many other centers also began to palliate these patients, but surgical results were often disappointing. This led many centers to question the wisdom of this approach. Because of the poor surgical results, many continued to counsel only compassionate care. Just two decades ago in 1983, Norwood and his coworkers reported in the *New England Journal of Medicine* the successful staged palliation of a patient with aortic atresia culminating in a Fontan procedure.[153] This provoked even more interest in the salvage of babies with hypoplastic left heart syndrome. Taking another approach, Bailey and his colleagues transplanted a baboon heart into Baby Fae, a newborn with the hypoplastic left heart syndrome, in 1985, but this baby did not survive.[154] This experience none the less ushered in the era of cardiac allotransplantation as another

dramatic therapy for babies with the hypoplastic heart syndrome, again experience pioneered by Bailey and his colleagues in Loma Linda, California. From the late 1980s some centers advocated the Norwood approach while others, neonatal cardiac allotransplantation, or both.[155] And some still counseled only compassionate care, a view considered by some unethical.[132]

But the Norwood procedure was not performed by surgeons in isolation. During the late 1970s and into the 1980s, centers around the world were gaining considerable experience in the Fontan operation, applying this operation to many forms of congenital heart disease (see Chapter 40). Many investigations were performed in various centers after first stage palliation. These shed light on the nature of the reconstituted ascending aorta; adequacy of repair of the distal aortic arch/coarctation; pulmonary arteries to define residual/recurrent obstruction, and the status of the atrial septum (restrictive or nonrestrictive).[132,133,156] There was considerable interest in right ventricular function and the implication of tricuspid regurgitation on short and medium-term outcome.[156,157] These findings led to continued refining and modification of surgical technique, with gradually improving surgical results. Various maneuvers were being employed to improve overall surgical results with the Fontan operation, including fenestration of the Fontan with later closure of the fenestration. Others felt that surgical outcome could be enhanced by staging to the Fontan (see Chapters 35 and 36). This staging took the form of a second operation interposed between the initial Norwood and the final Fontan.[158–164] The intermediate operation that staged to the Fontan was the performance of bidirectional cavopulmonary connection or hemi-Fontan with repair of associated anatomical hazards. The staging procedure unloaded the systemic right ventricle, changed its geometry, tended to improve a mild degree of tricuspid regurgitation and improved coronary dynamics.[165–167] These maneuvers were lauded by some as very important to reducing mortality at the time of the Fontan, but this opinion and experience were not universally shared (see Chapters 35 and 36).

By the late 1980s and early 1990s, some centers were achieving very reasonable surgical results with the Norwood procedure for babies with the hypoplastic left heart syndrome. Among those surgeons whose results were extolled included Norwood in Philadelphia; Bove of Ann Arbor, Castaneda and Jonas in Boston, Spray and his coworkers, Quaegebeur, Mee, Brawn and their respective colleagues, amongst others. As surgical results for the hypoplastic left heart syndrome continued to improve, the Norwood procedure was then applied to other forms of congenital heart disease with critical and complex forms of left ventricular outflow tract obstruction. Paralleling these accomplishments with the Norwood procedure, Bailey and his group continued to report an ever increasing and gratifying experience with neonatal transplantation.[168] Because donor hearts were often not immediately available for neonatal transplantation, the Loma Linda group became quite expert at keeping babies alive, some for weeks or even months, until a heart became available. Some required a maneuver to widen in a limited way a very restrictive atrial septal defect[33] and others while waiting for a donor organ, required stenting of the arterial duct as prostanoid therapy had become inadequate to prevent ductal closure.[169–171] As more experience with the Norwood procedure or cardiac transplantation accumulated, it became evident that those with a terribly restrictive atrial septum or in fact an intact atrial septum had an exceptionally poor outlook (Figs 31-3, 31-4).[31,33] This aspect led to a renewed interest in the nature of the pulmonary vascular bed in patients with the hypoplastic left heart syndrome. It became clear that a modest degree of obstruction at the atrial septum by promoting pulmonary venous hypertension had a salutory effect on pulmonary blood flow.[147] However Graziano and colleagues have published data suggesting that patients with the hypoplastic left heart syndrome and a restrictive atrial septal defect have pulmonary vascular abnormalities that place them at higher risk for

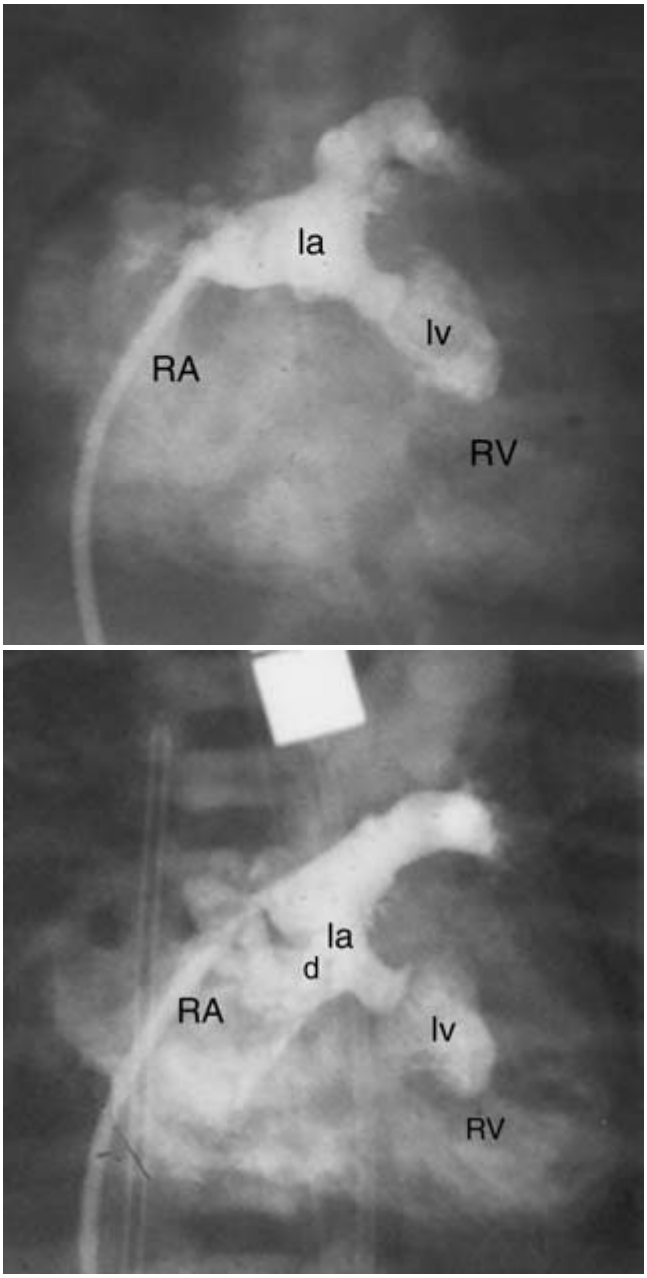

Fig. 31-3 Aortic atresia with severely hypoplastic mitral valve and restrictive patent foramen ovale. **A**. Injection into the tiny left atrium (la) visualizes the tiny left ventricle (lv). Only a small amount of left-to-right interatrial shunt is seen. **B**. Injection into the left atrium after balloon atrial septostomy demonstrates a large defect (d) created in the atrial septum. RA, right atrium; RV, right ventricle.

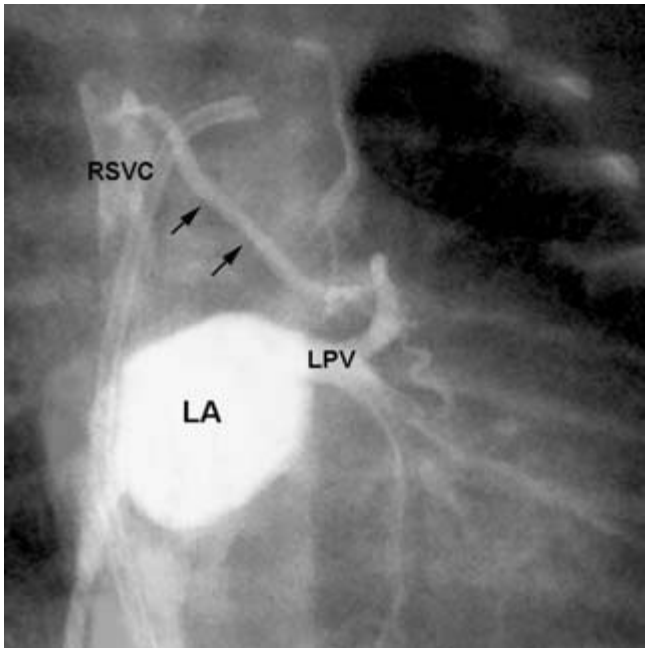

Fig. 31-4 Hypoplastic left heart syndrome with restrictive atrial septum. A collateral vein (arrows) arising from the left pulmonary vein (LPV) decompresses the hypertensive left atrium (LA) to the right superior vena cava (RSVC).

current surgical interventions.[147A] Kuhn and colleagues from Loma Linda with its extensive experience with transplantation as its primary form of therapy for these babies has suggested that those requiring atrial septal decompression are at greater risk for overall morbidity and mortality.[147B]

Today, one can only look back to the mid to late 1980s and wonder what all the fuss was about. Care givers were challenged by ethicists in offering therapy, or indeed withholding it.[172–179] There was no easy solution or answer and institutional choices were often mandated by their own individual experiences. Where surgical outcome was poor, it seemed that compassionate care was more commonly the usual option. During the same era, fetal echocardiography was providing a unique window to early recognition of congenital heart disease, and the choice for termination of pregnancy. In some parts of the world, fetal recognition and termination of pregnancy led to a reduced liveborn incidence of the hypoplastic left heart syndrome.[180] Attrition for the patient with the hypoplastic left heart syndrome continues to be substantial. Many families opt for termination of pregnancy once the fetal diagnosis is established. Sharland and her colleagues have had considerable experience with the prenatal recognition and outcome of fetuses with the hypoplastic left heart syndrome.[181–183] She has reviewed the fetal experience of Guy's Hospital in London, UK, with the hypoplastic left heart syndrome. The percentage of parents choosing termination of pregnancy was 75% in 1994; 55% in 1995; and 60% in 1996 and 1997.[182] Of the 354 cases with some form of the hypoplastic left heart syndrome in her series, there were 227 pregnancy terminations (64%), 22 intrauterine deaths (6.2%) 69 neonatal deaths (19.5%), and 6 deaths later in childhood (1.7%). Only thirty-five or 30% of the cohort survived. Some have asked whether prenatal diagnosis of the hypoplastic left heart syndrome effects preoperative status, surgical outcome and neurodevelopmental status.[184–190] The answer is not clear-cut. Chang and his colleagues some years ago suggested that prenatal diagnosis and earlier transport resulted in better preoperative condition and likely improved survival.[184] Mahle and his colleagues reviewed the very large experience of the Children's Hospital of Philadelphia.[186] With the use of multivariable analysis, their data indicated that prenatal diagnosis was associated with fewer adverse perioperative neurologic events than in those whose hypoplastic left heart syndrome had been diagnosed postnatally (odds ratio = 0.46). They go on to conclude that prenatal diagnosis has a favorable impact on treatment of patients who have hypoplastic left heart syndrome and are undergoing staged palliation, reducing as well early neurologic morbidity. In their experience, however, prenatal diagnosis was not associated with reduced hospital mortality. Kumar and coworkers also found that prenatal diagnosis did not improve the outcome of intervention when compared to those diagnosed postnally.[187] But prenatal diagnosis did improve the preoperative status of babies with the hypoplastic left heart syndrome, a finding supported by Satomi and coworkers.[185] This issue has also been addressed by Tworetzky and his colleagues.[188] They concluded that prenatal diagnosis of hypoplastic left heart syndrome was associated with improved preoperative clinical status and with improved survival after first-stage palliation in comparison with patients diagnosed after birth. Allan and her colleagues reviewed the experience of the Columbia Babies Hospital in terms of outcome after prenatal diagnosis of the hypoplastic left heart syndrome.[189] There was a survival rate of 70% in infants undergoing surgery with no complicating features; a 50% survival of all the surgical candidates; and only a 37.5% survival from an intention to treat position.[189] Brackley and coworkers reviewed the outcome of all 87 fetuses with the hypoplastic left heart syndrome referred to the Fetal Medicine Unit at Birmingham Women's Hospital between 1994 and 1999.[190] They were referred at a median gestational age (95% CI) of 23 (19–37) weeks. Of these, 53 (61%) chose prenatal karyotyping. The overall frequency of abnormal karyotype was found in 7 of 59 cases (12%) and associated structural anomalies in 18 of 87 (21%). After counseling, 38 of 87 couples (44%) chose termination of pregnancy. Of the remaining 49 fetuses, 11 (23%) were not considered for postnatal surgery because of parental choice and they died after compassionate care. Of the 36 babies who had surgery postnatally, only 12 survived (33%). Thus they recorded a survival rate of 38% for the stage 1 Norwood procedure in the prenatally diagnosed patients with hypoplastic left heart syndrome seen in their center. These data suggest that at the point of prenatal detection, the overall survival rate for fetuses with hypoplastic left heart syndrome is 25% (if terminated pregnancies are excluded). Friedman and his colleagues have provided a useful summary of the issues related to the prenatal diagnosis of the hypoplastic left heart syndrome.[186A]

Even today there remains considerable attrition for those fetuses and liveborn babies identified with the hypoplastic left heart syndrome. Termination of pregnancy, decision for nontreatment of the liveborn, mortality at the various surgical procedures and between the stages, and morbidity and mortality after Fontan or transplant all serve to reduce the outcome of the entire cohort.[162,180–202] The inevitable outcome of so-called compassionate care is death as well. For those babies listed for transplant, death on the waiting list can be 20% or higher, with a 30-day surgical mortality of 10–15%.[203–205] The post-transplant survival for patients is reasonably good, with 70–80%, or even

higher at 5 years. Dr Lori West of the Toronto Hospital for Sick Children introduced the concept of ABO-incompatible heart transplants in the neonate and young infant and has reported her initial experience with 10 patients with encouraging results.[206] This strategy may reduce the time on the waiting list and pre-transplant morbidity and mortality as well. Clearly at this time donor availability remains an important issue.

There remains discussion and debate as to which is the better surgical strategy: staging with the Norwood to the Fontan, or transplantation.[207,207A] Some patients starting out on a transplant algorithm may switch to a Norwood–Fontan tract if a heart does not become available, and some having undergone first stage Norwood palliation or second stage palliation will cross over to a transplant algorithm because of poor right ventricular function, severe tricuspid regurgitation; pulmonary artery hypertension, etc. Some have advocated decision analysis in defining the optimum treatment strategy.[208] Gutgesell and Massaro reported the results of management strategies of 636 neonates with the hypoplastic left heart syndrome in a consortium of 40 university hospitals from 1989 to 1993.[202] In 374 patients (59%), no surgical procedure was carried out, and presumably all these patients died. A Norwood procedure was performed in 222 with 53% mortality, and a cardiac transplant in 40, with 42% mortality. Gutgesell and Gibson have recently reported[202A] the results of the management of the hypoplastic left heart syndrome from a University Hospital Consortium from 1990 to 1999, thus slightly overlapping with their earlier report.[202] Of the 2264 patients with the hypoplastic left heart syndrome admitted to hospitals participating in this study (27 institutions in 1990 and 56 by 1999), 1203 underwent a Norwood procedure with a 42% mortality.[202A] Cardiac transplantation was performed in 72 with 38% mortality. Interestingly, in the hospitals participating as members of the University Hospital Consortium, the proportion of patients managed by the Norwood procedure increased from 43% during the first half of the decade to 59% in the second half, with a corresponding decrease in the proportion managed either by transplantation or non-intervention. Five of the participating institutions performed > 50 Norwood procedures during the study period, and a mortality rate ≤ 40% was achieved by all 5, and by 9 of 40 institutions performing < 50.

Some years ago the Congenital Heart Surgeons Study addressed intermediate survival in neonates with aortic atresia.[201] Three hundred and twenty-three neonates with aortic atresia were entered into a 21-institution prospective, nonrandomized study between January 1, 1994 and January 1 1997.[201] Three protocols were used: (1) staged reconstructive therapy with initial Norwood palliation concluding in the Fontan in 253; (2) heart transplantation in 49; (3) non-surgical management in 21. For the patients entered into the two surgical protocols, survival at 1, 3, 12, 24, and 36 months after entry was 67%, 59%, 52%, 51%, and 50%, respectively. A multivariable analysis found incremental risk factors for death at any time after entry to be lower birthweight (P = 0.04); associated noncardiac anomaly (P = 0.007) and entry into the non-surgical protocol (P < 0.0001). In the overall study, there did not appear to be an important difference in the outcome of the two surgical strategies. Differences were recognized, however, between those institutions designated as high or low risk ones.[201] These observations were recently extended by the 2003 publication of Ashburn and his colleagures for the Congenital Heart Surgeons Study who reported on the outcomes of 710 neonates with either critical aortic stenosis or aortic valve atresia undergoing Norwood palliation.[202B] These patients were enrolled prospectively by 29 participating institutions between 1994 and 2000. Overall survivals after the Norwood operation were 72%, 60% and 54% at 1 month, 1 year and 5 years, respectively. Risk factors for mortality included lower birth weight, smaller ascending aorta, older age at Norwood operation and a number of institutional and procedural variables. Of the neonates surviving initial Norwood palliation, risk factors for death occuring before subsequent transition included younger age at cavopulmonary shunt and need for right atrioventricular valve repair.

Cohen and Allen have reported data from the Pediatric Cardiac Care Consortium (PCCC).[209] In this database, from 1984 to 1995, 438 patients with the hypoplastic left heart syndrome underwent as an initial operation either a Norwood procedure or cardiac transplant. In 380 of the 438, the initial operation was the Norwood procedure, and of these 270 (55%) died postoperatively, and 170 survived. Mortality was greatest for the smallest infants; 87.5% for those under 2.5 kg. and 16.7% for those over 5.0 kg. In this regard, Weinstein and his colleagues reviewed the experience of early survival of infants weighing 2.5 kg or less undergoing first-stage reconstruction for hypoplastic left heart syndrome, finding an early mortality within 30 days of operation or before hospital discharge of 51%.[210] Of the 170 survivors of first-stage palliation in the PCCC, 20 died following another operation. These 150 survivors underwent an additional 60 operations with several more deaths. Thus, of the 380 infants undergoing staged palliation, 230 died following an operation, for a cumulative operative mortality rate of 60%. Cardiac transplantation was the initial operation in 58 neonates, and 17 (29%) died. In data from the PCCC, the mortality rate for the Norwood procedure declined to 45.6% for 79 operations performed in 1994.[209] Pylees and colleagues have recently extended the experience of the Pediatric Cardiac Care Consortium with the outcome of staged palliation of the hypoplastic left heart syndrome. In the interval from 1985 to 1989, 38% survived first stage palliation; 1990–1994, 45%; and from 1995 to 1999, 49% survived first stage palliation. For the entire cohort of 1147 babies with the hypoplastic left heart syndrome enrolled from 1985 to 1999, 46% survived first-stage palliation. Second stage palliation survival improved from 74% in 1985–89 interval to 94% in 1995–99. Fontan survival was 81% in the earliest interval, improving to 97% in the 1995 to 1999 interval. Interestingly in this analysis, stage 1 survival correlated poorly with center volume in the group possessing a maximum of 9.6 cases/year.[209A]

Indeed, experience reported from a number of centers has reported declining mortality rates for first-stage palliation in recent years.[193,195–198,200,201] Jenkins and her colleagues published in 2000 interesting data comparing the two treatment strategies for the hypoplastic left heart syndrome.[211] They obtained data on 231 infants with hypoplastic left heart syndrome, born between 1989 and 1994 and intended for surgery from four pediatric cardiac surgical centers. The patient's status at last contact was used for survival analysis and mortality at one year for risk factor analysis were the outcome measures. Survival curves showed improved survival for patients intended for transplantation over patients intended for staged surgery. One-year survival was 61% for transplantation and 42% for staged surgery (P < 0.01); 5-year survival was 55% and 38%, respectively (P < 0.01). Survival curves adjusted for preopera-

tive differences were also significantly different ($P < 0.001$). Waiting-list mortality accounted for 63% of first-year deaths in the transplantation group. Mortality with stage 1 surgery accounted for 86% of that strategy's first-year mortality. Birth weight < 3 kg (odds ratio [OR] 2.4), highest creatinine > or = 2 mg/dL (OR 4.7), restrictive atrial septal defect (OR 2.7) and, in staged surgery, atresia of one (OR 4.2) or both (OR 11.0) left-sided valves produced a higher risk for 1 year mortality. Their data showed that transplantation produced significantly higher survival at all ages up to 7 years. Furthermore, patients with atresia of one or both left-sided valves did poorly in staged surgery and had significantly better survival with transplantation.[211] Chang and colleagues have addressed the clinical management of infants with the hypoplastic left heart syndrome treated in the United States from 1988 to 1997 using the National Inpatient Sample Dataset.[211A] For the entire time period they enrolled 1986 patients with the hypoplastic left heart syndrome, with 812 in-hospital deaths (40.9%). The in-hospital mortality rate decreased from 54.4% in 1988 to 38.1% in 1997. The proportion of patients treated with the Norwood operation increased from 8% in 1988 to 34% in 1997. The proportion of patients dying in hospital without surgery decreased over time. Their data also showed a lower mortality for patients undergoing cardiac transplantation compared with the Norwood procedure (26.2% vs. 46%). Tweddell and his colleagues have shown a remarkable improvement with first stage palliation, with hospital survival in the years 1992 to 1996 of 44%, compared to 93% from July 1996 to October 2001.[211B] Survival to stage two palliation also significantly improved in the current era, 81% (66/81) vs. 44% (15/34), $P < 0.01$. Anti-inflammatory treatment strategies demonstrated improved survival by univariate analysis ($P < 0.001$). Multivariate analysis identified continuous venous oxygen saturaion monitoring as a factor favoring first stage palliation survival ($P = 0.02$) and use of POB as a factor favoring survival to stage two palliation ($P = 0.003$). In the current era shorter duration of deep hypothermic circulatory arrest was associated with improved survival to second stage palliation ($P = 0.02$). In this experience improved survival following first stage Norwood palliation was achieved with strategies that allowed for early identification of decreased systemic output and the use of afterload reduction to stabilize systemic vascular resistance and therefore the pulmonary to systemic flow ratio.

The Norwood circulation is for many infants unstable with the potential for adverse events especially in the first year of life.[191,192] Retrospectively, data from the Children's Hospital of Philadelphia were reviewed to determine the incidence of unexpected death among 536 patients with hypoplastic left heart syndrome who were discharged to home after stage I surgical procedure.[192] To identify potential risk factors, a nested case–control analysis was undertaken. Unexpected death occurred in 22 of 536 patients (4.1%) discharged to home after stage I surgical procedure. The median age at unexpected death was 79 days (range, 25 to 227 days). Seizures preceded cardiac arrest in 2 patients, and ventricular arrhythmias were documented in 3 additional patients during attempted resuscitation. Autopsy studies were performed in 12 patients and identified residual lesions that may have contributed to death in 2 patients. In multivariate analysis documented perioperative arrhythmia and earlier year of stage I surgical procedure were associated with an increased risk for unexpected death ($P = 0.03$ and $P = 0.04$, respectively). There were 4 additional patients who had unexpected death after subsequent cavopulmonary operation at a median age of 1.6 years (range, 0.9 to 3.8 years). Unexpected death occurred in > 4% of patients with hypoplastic left heart syndrome who were discharged to home after stage I surgical procedure and was most common in the first several months of life. This group concluded that factors that may contribute to unexpected death included residual lesions, arrhythmias, and neurologic events, although in the majority of cases the cause remained largely unknown. The group from the Children's Hospital in Boston studied the post-mortem findings of 122 patients who died after undergoing the Norwood procedure from 1980 to 1995 to establish the causes of death and consider their therapeutic applications.[191] The most important causes of death were found to be impairment of coronary perfusion (33 patients, 27%); excessive pulmonary blood flow (23 patients, 19%); obstruction of pulmonary arterial blood flow (21 patients, 17%); neoaortic obstruction (17 patients, 14%); right ventricular failure (16 patients, 13%); bleeding (9 patients, 7%), infection (6 patients, 5%); tricuspid or common atrioventricular valve dysfunction (6 patients, 5%); sudden death from presumed arrhythmias (6 patients, 5%); and necrotizing enterocolitis (3 patients, 3%). In 26 patients (21%) the leading causes of death after the Norwood procedure were found to be largely correctable surgical technical problems associated with perfusion of the lungs (36%), of the myocardium (27%), and of the systemic organs (14%).

Data recently published from Toronto reported evolving strategies and improving outcomes of the modified Norwood procedure over the past decade.[193] The overall 5-year survival rate for 171 infants undergoing staged reconstruction was 43%. The mortality rate for first stage reconstruction from 1990 through 1993 was 59%; in the period from 1994 through 1997, 39%, and from 1998 into 2000 19%. Kaplan–Meier survival curves at 1 month, 1 year, and 5 years were at follows: 43%, 31%, and 28% in the earliest era; 60%, 49%, and 45% in the middle era, and 80% at 1 month and 68% at 1 year from 1998 into 2000.[193] In Cox proportional modeling, the only significant independent risk factors associated with an increased risk of time-related death were earlier date of Norwood operation; lower weight at the Norwood operation, and preoperative use of mechanical ventilation. After controlling for these variables, no other variable was associated with total mortality. There was a trend toward an increased risk of mortality with greater degrees of preoperative tricuspid regurgitation.[193] De Rose and colleagues described the findings of a newborn dying at first stage palliation with intractable left ventricular ischemia. Causal to this was severe hypoplasia of the left coronary artery and an abnormal coronary artery branch contributing to a myocardial steal. We and others have documented thrombus in the aortic root which occluded one or both coronary ostia and acute shunt occlusion has been documented clinically and at post-mortem.[191,192,212,213] Contributing to morbidity and mortality after first-stage palliation is recurrent obstruction of the aortic arch.[191,192,213–222] We have documented precoronary stenosis in the reconstructed ascending aorta and have surgically revised this area successfully.[223] Evidence has been provided that the reconstituted transverse aortic arch grows after the Norwood operation.[224] The incidence of coarctation after stage I Norwood procedure varies between 11% and 37% and this contributes to late morbidity and death after this operation (Fig. 31-5).[214–221] Balloon angioplasty has been shown to be very effective in treating this complication.[214–221] One should be aware that in

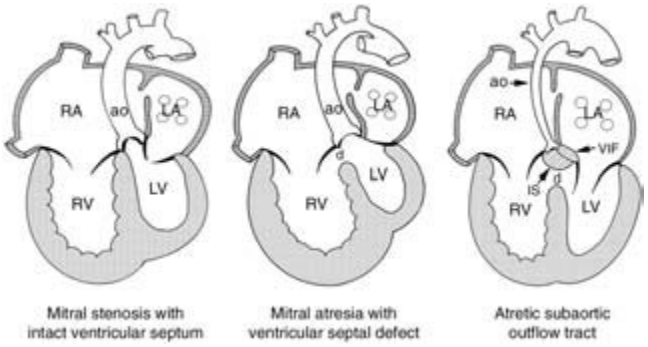

Fig. 31-5 Aortic atresia with normal left ventricle. The left ventricle (LV) can be normally developed in the presence of aortic atresia. ao, aorta; d, ventricular septal defect; LA, left atrium; RA, right atrium; RV, right ventricle; VIF, ventriculoinfundibular fold.

some patients acute cyanosis can develop following balloon angioplasty of recurrent aortic arch obstruction after the Norwood operation.[219] This likely reflects the response to the acute drop in driving pressure across the systemic-to-pulmonary artery shunt. In those patients with an aberrant right subclavian artery, blood pressure measurements from upper and lower limbs may be confusing because the origin of both vessels may be compromised in the repair of the distal aortic arch. Similarly, the origin of the innominate artery can be compromised after stage I palliation as reported by Garabedian and colleagues, promoting an innominate artery steal.[225] Rarely in the patient with aortic atresia the innominate artery will be isolated as in the patient reported by Papagiannis *et al.*[94] In any patient not doing well after first stage palliation it is mandatory that the distal aortic arch be completely imaged. In the presence of the tortuosity of the reconstructed aortic arch, cross-sectional echocardiography and color Doppler may not be adequate to define the status of the aortic arch.[226] Fraisse and coworkers advocate angiographic imaging. We would often first perform MRI-imaging and then either to treat or to confirm we would resort to an invasive procedure.[217] Acute shunt thrombosis is sadly a reality for some babies after first stage palliation, contributing to the attrition.[191–193] This seems more common in the smaller shunt and when there is associated pulmonary artery stenosis. There has been some experience with aortopulmonary shunt reconstitution using balloon angioplasty and placement of an endovascular stent.[227,228] Tricuspid valve regurgitation also exerts its toll on patients with the hypoplastic left heart syndrome.[80,151,159,160,191,192,201] Virtually all studies addressing tricuspid valve form and function in patients with the hypoplastic left heart syndrome showed that important regurgitation affected in a negative way outcome at the Fontan (see Chapter 47). Intrinsic anatomic abnormalities of the tricuspid valve are more common than previously thought, and certainly tricuspid regurgitation is often both functional and anatomic in origin.[80,151] Mild tricuspid regurgitation may be reduced in severity by those surgical maneuvers reducing right ventricular volume overload, namely the hemi-Fontan or the bidirectional cavopulmonary shunt.[159,160,191,192,195–199,229] There is less clinical evidence that these maneuvers exert an influence in those patients with severe tricuspid regurgitation, and surgical repair/annuloplasty or replacement is necessary if these patients are to become candidates for the Fontan.[230–233] The group from Ann Arbor has had a large experience with tricuspid valvuloplasty in patients with the hypoplastic left heart syndrome, describing the pathology as either or both abnormal leaflet morphology or incomplete leaflet coaptation.[231,232] Some patients will certainly be improved by these procedures and will become satisfactory candidates for the Fontan, while others will cross over to a transplant protocol.

In the evolving strategies to enhance first-stage outcomes, some have revisited bilateral pulmonary artery banding with stenting of the arterial duct as first-stage palliation.[233B] This limited experience allowed survival in some patients to heart transplantation or to neoaortic reconstruction and a bidirectional cavopulmonary shunt. Even more recently, Pizarro and Malec and their colleagues have reported that the use of a right ventricle to pulmonary artery conduit at the first stage reconstruction improves outcome.[233C,D] This procedure conferred better and more stable postoperative hemodynamics as the patient is not shunt-dependent. While their observations about enhanced early outcome seem compelling, the impact of this maneuver on the function of the single, systemic right ventricle must be carefully defined. This group reported much improved hemodynamics using this approach.[233C,D] This issue is particularly germane for the patient with the hypoplastic left heart syndrome who will undergo a Fontan procedure. Concern about the morphologically right ventricle as the systemic ventricle has been discussed elsewhere in this volume (see Chapters 25A and 26A). Pearl and his colleagues have provided a recent discussion of the many surgical strategies employed for patients with the hypoplastic left heart syndrome.[233E] Ishizaka and colleagues have also reported the role of bilateral pulmonary artery banding to resuscitate the newborn with the hypoplastic left heart syndrome.[233F]

Any number of risk factors have been identified for poor outcome at the initial staging Norwood operation.[233A] These include low birth weight, a diminutive ascending aorta; atresia of both aortic and mitral valves as compared to those with patent valves; severe extracardiac anomalies; preoperative clinical status; Turner syndrome, right ventricular dysfunction, age at the time of first stage palliation, etc. Most now exclude patients with severe extracardiac malformations from either surgical protocol. Turner syndrome has been shown to be a risk factor for poor outcome of the Norwood procedure.[234] Reis and his colleagues reviewed the implications of this association from the 406 cases of hypoplastic left heart syndrome seen from 1990 to 1997 at the Children's Hospital of the University of Michigan.[227] Ten (2.5%) also had Turner syndrome. Nine infants were delivered at term and one at 36 weeks. The mean (± SD) gestational age at delivery was 38 ± 1.2 weeks, and mean (± SD) birth weight was 2991 ± 438 g. The karyotype was 45, X in seven cases, and 45, X mosaic in three. Most infants had dysmorphic features at birth. All 10 infants had first-stage reconstruction surgery for hypoplastic left heart syndrome. Only two survived and underwent second-stage palliation; both are alive currently, although with significant medical problems. From this experience they concluded that while staged reconstruction surgery has improved survival for neonates with isolated hypoplastic left heart syndrome, for those with Turner syndrome, survival appears markedly reduced.[234] There is not general agreement as to the issue of the tiny ascending aorta as a risk factor.[132,201] Some do not open the diminutive ascending aorta to its root in the Norwood repair as initially advocated by Norwood,[235,236] but rather connect the pulmonary trunk to the undersurface of the transverse aortic arch, thereby "neutralizing" this

factor.[134,198] Right ventricular dysfunction has not proven to be a risk factor for first stage palliation, but has proven a risk factor at staging and at subsequent Fontan.[157] There are certain patients with very severe right ventricular dysfunction even after effective resuscitation, or those with a prenatal right ventricular myocardial infarction,[237] and both groups would be anticipated to do poorly.[160,161,195–198,201] Older age at the time of first stage palliation has been suggested to be a risk factor for poor outcome, although there is not unanimity of opinion about this.[195,201,238] Pizarro and colleagues have published data that low birth weight babies have an increased early surgical risk but have acceptable intermediate survival for subsequent palliation including the Fontan.[201A] This group concludes that prematurity and low birth weight should not contraindicate Norwood palliation.

There is ever increasing experience both with outcomes of the bidirectional cavopulmonary shunt and with the Fontan procedure for the hypoplastic left heart syndrome.[183,193,196,201,239–243] As we discuss in Chapter 35, mortality at the intermediate staging operation is in the range of 5–6%.[160,165,201] Mosca and his colleagues reported the Ann Arbor experience with the Fontan procedure in 100 consecutive patients with the hypoplastic left heart syndrome between February 1992 and April 1998.[239] The hospital survival for the entire cohort was 89% (95% CL, 83% to 95%). During this time period, two different surgical techniques were used: cardiopulmonary bypass with moderate systemic hypothermia, and in the latter half of the experience, circulatory arrest with profound hypothermia. Survival was 98% for the second technique, and 79% for the first. Azakie and his colleagues from the Toronto Hospital for Sick Children reported the results of the Fontan procedure in 45 patients palliated with the Norwood procedure from 1993 to 2000.[242] There were 2 early and 2 late deaths in this modest-sized series. Mahle and his colleagues have reviewed a 15-year experience of the Children's Hospital of Philadelphia with 840 patients with the hypoplastic left heart syndrome who underwent first stage palliation between 1984 and 1999 focusing on survival.[243] The 1-, 2-, 5-, 10-, and 15-year survival for the entire cohort was 51%, 43%, 40%, 39%, and 39%, respectively. Late death occurred in 14 of the 291 patients discharged to home after the Fontan procedure, although only 1 patient has died beyond 5 years of age. Heart transplantation after stage I reconstruction was performed in 5 patients. Later era of stage I surgery was associated with significantly improved survival ($P < 0.001$). Three-year survival for patients undergoing stage I reconstruction from 1995 to 1998 was 66% vs. 28% for those patients undergoing surgery from 1984 to 1988. Age > 14 days at stage I and weight < 2.5 kg at stage I were also associated with higher mortality ($P = 0.004$ and $P = 0.01$, respectively). Other variables, including anatomic subtype, heterotaxia, and age at subsequent staging procedures, were not associated with survival. Late death after the Fontan and the need for cardiac transplantation were uncommon in this very large experience.[243] The overall survival from a modest-sized series of patients with the hypoplastic left heart syndrome diagnosed antenally from 1995 to 2000 was 48%, with virtually all the surgical mortality occurring at the Norwood operation.[190] In another series of prenatally diagnosed hypoplastic left heart syndrome reported by Munn and colleagues, the survival rate following surgery for infants felt to be the best candidates was only 25%.[244]

In follow-up, the survivors of the Fontan will experience the entire range of potential complications described in these patients (see Chapter 37). Because the morphologically right ventricle supports the systemic circulation in the patient with the hypoplastic left heart syndrome, the long-term performance of the single right ventricle is of considerable interest. The form and function of the morphologically right ventricle as the systemic ventricle after atrial repair of complete transposition has been dealt with in Chapter 25A. In addition, progressive dysfunction of the systemic morphologically right ventricle in patients with double discordance has been amply documented (see Chapter 26A). In this regard, Van Praagh *et al*. has summarized those reasons why the morphologically right ventricle is inherently disadvantaged as the systemic ventricle.[245] Perhaps there is even more to be concerned with in the Fontan survivor group with the hypoplastic left heart syndrome. Many of these patients do indeed have only a single right ventricle. Others have a small, hypertensive left ventricle with the potential for ventriculocoronary connections and coronary artery occlusive pathology. In this regard, the study of Sugiyama and colleagues is relevant.[246] Their findings suggested that ventricular function appeared to be greatly influenced by left heart structure. The presence of larger left ventricular muscle bulk and frequent myocardial damage seen in mitral stenosis/aortic atresia seems disadvantageous to right ventricular end-diastolic volume and right ventricular wall motion. Fogel and his colleagues have reported a number of differences in contractility in patients with single right ventricles compared with systemic right ventricles in a dual-chamber circulation.[247] The long-term implications of Fogel's findings are unclear at this time. However publications from Matsuda and Mahle and their respective coworkers do provide worrisome information about the functionality of the single right ventricle.[248,249] Mahle and his colleagues published their findings in 2001 showing that the systolic and diastolic properties of the functionally single right ventricle differ considerably from those of the normal systemic ventricle.[248]

In the cascade of data to be included in any outcome analysis of patients undergoing univentricular palliation is the issue of neurodevelopmental status. One should not be surprised that neurodevelopmental outcome may not be entirely normal when one reflects on the findings of Natowicz, Glauser, Rogers and their respective colleagues.[56–59] A number of studies have addressed neurodevelopmental outcome of patients who have undergone the Fontan procedure and more specifically those with the hypoplastic left heart syndrome (see Chapter 36). First, as reminded by Limperopoulos and her colleagues neurodevelopmental abnormalities are common in young infants with congenital heart defects and are often present before as well as after open heart surgery.[250–252] Mahle and his colleagues from the Children's Hospital of Philadelphia studied the outcome of 115 school-aged children with the hypoplastic left heart syndrome who had undergone staged palliation before 1992.[253] Over 30% of patients were receiving some form of special education. Although the majority of patients scored within the normal range on standardized neurocognitive testing, the median full-scale IQ (86) was significantly lower than the general population. Of further concern was that 18% of the subjects had IQ scores in the mentally retarded range. Minor neurologic abnormalities were also detected in 55% of patients and 60% had problems with attention. Multivariate analysis revealed the occurrence of clinical seizures at the time of presentation was associated with lower full-scale IQ scores. Similar findings were published by Goldberg and her colleagues who showed that the

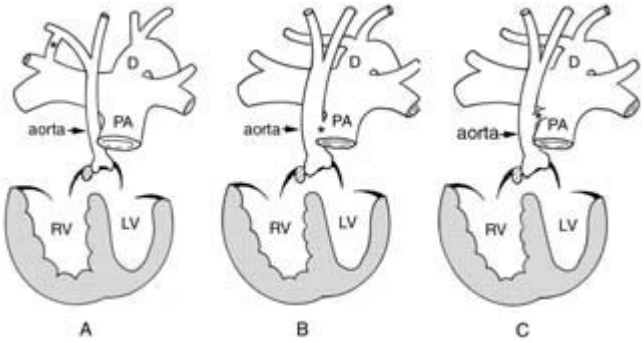

Fig. 31-6 Aortic atresia with interrupted aortic arch. The source of blood supply (asterisk) to the ascending aorta is the right-sided arterial duct (**A**), aortopulmonary window (**B**) or fistulous tract of the fifth aortic arch origin (**C**). LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

hypoplastic left heart syndrome patients scored less well on the Full Scale Wechsler test than patients with other forms of single ventricle pathology.[254] None the less, what a drama since the first description of the physiology of this disorder in 1851;[255] the initial descriptive morphologies and clinical descriptions of the 1950s, attempts at palliation in the 1960s and 1970s, and the first Fontan in 1983. There is no doubt about it: despite ongoing challenges with and for patients with the hypoplastic left heart syndrome [256] we must value the survivors.[257] The learning curve for many of us was steep, but surgical and medical ingenuity has made it clear that aortic atresia is no longer the "worst heart disease."[1]

Aortic atresia and normal left ventricle

Aortic atresia is not synonymous with left ventricular hypoplasia. There are a group of patients with aortic atresia and a normal left ventricle (Fig. 31-5),[70,97–100,102–104,258–262] and > 25 years ago we speculated that some of these patients may be candidates for ventriculoaortic reconstitution.[71] Some of these patients have a complex form of univentricular heart or double discordance.[109–121] However there is a group with normal situs and connections, usually a large, malalignment-type of ventricular septal defect, and aortic atresia.[70,258,260] Although a variety of ventricular septal defect morphologies have been described, the most common is characterized by caudal displacement of the infundibular septum that fused posteriorly with the left-sided ventriculoinfundibular fold ventricle (Fig. 31-5C).[70,260] This completely blocks the subaortic vestibule. The combination of aortic atresia with a normal left ventricle has been described in combination with an associated interruption of the aortic arch. Blood supply to the ascending aorta has been mediated by an aortopulmonary window,[62,98,99,104] right-sided arterial duct,[100] and proximal aortopulmonary fistulous connection (likely a fifth aortic arch with a systemic-to-pulmonary artery connection) ventricle (Fig. 31-6).[102,103]

In 1981, Norwood and Stellin reported a reparative operation for a patient with aortic atresia, interruption of the aortic arch, ventricular septal defect and bilateral arterial ducts.[100] The ventricular septal defect was patched; the aortic arch reconstituted, and an apical left ventricle–descending aorta conduit was used to provide continuity between the left ventricle and the systemic circulation. Duffy and coworkers next reported in 1983 the initial palliation of a baby with aortic atresia and ventricular septal defect at 23 days of age.[263] The first procedure included bilateral banding of the branch pulmonary arteries similar to the patient reported from Toronto in 1977,[70] and replacement of the ductus arteriosus with a Goretex conduit. At 23 months of age, corrective surgery was accomplished by closure of the ventricular septal defect, insertion of a valved conduit between the apex of the left ventricle and the subdiaphragmatic aorta, removal of the pulmonary artery bands and division of the pulmonary–aortic conduit. In follow-up the patient had a mild coarctation of the aorta but remained asymptomatic at 2 years of age.

A single-stage repair in the neonate without the use of an apical left ventricle-to-descending aortic conduit was first reported by Austin and colleagues in 1989,[264] and there have been a number of other reports since that time.[265–271] Repair is accomplished by tunneling the left ventricle through the ventricular septal defect to the pulmonary artery. The pulmonary

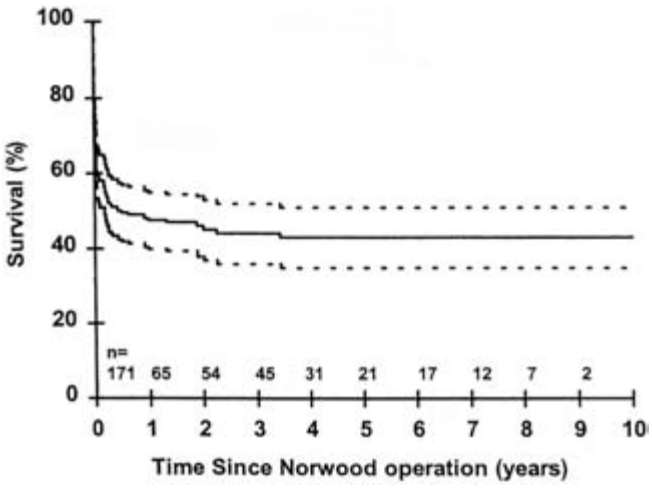

Fig. 31-7 Kaplan–Meier survival curve for 171 patients undergoing modified Norwood procedure at Toronto's Hospital for Sick Children from 1990 to 2000. The overall mortality rate was 41%. (Reprinted rom Azakie *et al.*,[193] Copyright (2001), with permission from the Society of Thoracic Surgeons.)

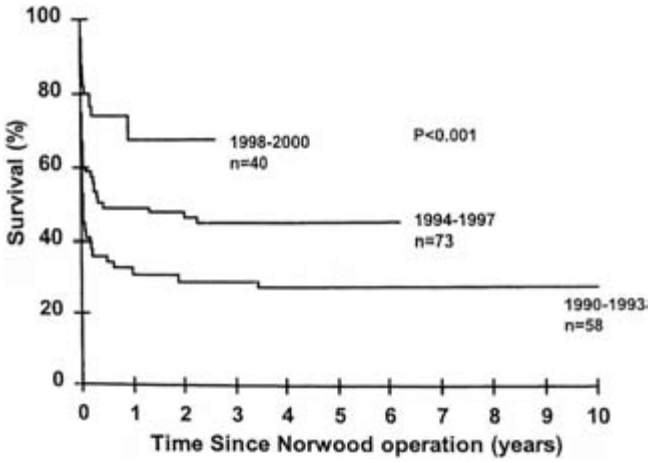

Fig. 31-8 Data from Toronto's Hospital for Sick Children. Kaplan–Meier curves demonstrate improving outcome between the different eras. (Reprinted from Azakie *et al.*,[193] Copyright (1999), with permission from the Society of Thoracic Surgeons.)

trunk is divided and the proximal pulmonary trunk is connected to the ascending aorta. Continuity between the right ventricle and distal pulmonary artery confluence is achieved with a conduit. We have experience with the repair of six patients with one death. The late mechanical issues relate to the performance of the native pulmonary valve in the systemic circulation and the "usual" problems encountered with a conduit in the neonate and infant. There is one patient with aortic atresia, ventricular septal defect and discordant ventriculoarterial connections who underwent a successful one-stage biventricular repair using a similar technique.[272]

Patients with the hypoplastic left heart syndrome complicated by absent aortic valve leaflets have tended to do very poorly at first-stage Norwood and cardiac transplantation is a better treatment strategy.[273–278] Finally, as we will discuss elsewhere (see Chapters 25A and 37), patients with a single or systemic right ventricle are known to develop ventricular dysfunction and heart failure, indeed a sobering and concerning consideration for those on or those who have completed Fontan palliation.[279] One must be impressed by ever-improving results with Norwood palliation as shown in Toronto (Figs 31-7, 31-8) and elsewhere.[163,193,198,211B] Yet a recent survey showed that given a prenatal diagnosis of the hypoplastic left heart syndrome 48% of physicians surveyed would terminate pregnancy, only 22% would continue pregnancy and 30% were uncertain. Given a neonatal diagnosis, physicians were evenly split between surgical treatment, comfort care without surgery, and uncertainty.[280]

Thus in the > 25 years since systematic palliation of the patient with hypoplastic left heart syndrome began:

- Hearts with typical morphology of the hypoplastic left heart syndrome are amenable to univentricular palliation and there is increasing experience with staged reconstruction concluding in the Fontan operation.
- There is still discussion and evolution as to what approach affords the best first stage palliation. There is increasing experience in catheter-mediated palliation and as well evolution from an arterial shunt with its intrinsic instability to a right ventricle to pulmonary artery conduit to afford better postoperative hemodynamics. Some have reverted to bilateral pulmonary banding, but whether this approach will gain wider acceptance is only speculative.
- Surgical results of first-stage palliation continue to improve in many centers.
- Termination of pregnancy will continue to have an effect on liveborn prevalence of this disorder.
- In those patients undergoing staged palliation, there is attrition at and between every stage, with most of the attrition at or about and between the first and second stages.
- Neonatal cardiac transplantation also affords reasonable palliation. It is unclear at this time whether staged palliation or transplantation in the long term will be most advantageous to the patient born with hypoplastic left heart syndrome.
- For patients surviving staged palliation, a morphologically right ventricle will be the systemic ventricle. Thus many of the concerns about the long-term functionality of the morphologically right ventricle are similar to those of patients with transposition of the great arteries surviving the Mustard or Senning operation (see Chapter 25A) or the patient with double-discordance who has undergone physiologic repair (see Chapter 26A).
- Cohen and colleagues have found that amongst patients followed up to 21 years after staged reconstruction for the hypoplastic left heart syndrome the neo-aortic root progressively dilated out of proportion to body size over time, with 98% of their cohort having a Z-score > 2 at most recent follow-up.[281] Neo-aortic regurgitation was present in 61% of patients at most recent follow-up, with progression over time in about half of their study group (49%). However, neo-aortic regurgitation was more than mild in only a few patients. They found that significantly larger neo-aortic root Z-scores were observed in patients with any degree of neo-aortic regurgitation at most recent follow-up.
- As in any patient undergoing repair of a complex cardiac malformation in the neonatal period using profound hypothermia and cardiac arrest, longitudinal neurodevelopmental and cognitive function assessments are important.
- Considerable new knowledge has evolved directly from the challenges to salvage babies with the hypoplastic left heart syndrome.
- This malformation complex should no longer be considered the "worst heart disease."[1]

Double-Inlet Ventricle

Double-inlet ventricle is the most common form of so-called "single or univentricular hearts." In double-inlet ventricle, the ventricular inlet is unseptated (Fig. 32-1). It sounds so simple, ventricular septation, for hearts with basically one unseptated ventricular chamber, but the results, early and late for the most part were disappointing, and thus this approach has been largely abandoned.[1–8] Something better had to come along, and it did: atrial separation and an atriopulmonary connection, the Fontan operation or complete right heart bypass, first performed in 1968 and with the wisdom of restraint published in 1971.[9–11] This operation dramatically altered the outcomes for many patients with a "single ventricle" malformation. The thrust of contemporary management strategies is to protect the integrity of the myocardium and pulmonary vascular bed so that the patient will meet the criteria for the Fontan operation (see Chapter 36). Fundamental to this strategy then is to preserve the systolic and diastolic function of the myocardium, prevent disproportionate myocardial hypertrophy and disadvantageous ventricular compliance, maintain functional integrity of one atrioventricular valve, and very importantly to protect the pulmonary vascular bed from hypertensive changes.[8,9] Perhaps as well, it is important to maintain the functional integrity of the pulmonary valve in those patients with a single ventricle malformation either with or at risk for subaortic stenosis for later palliation.[12–16]

Prevalence

The prospective Bohemia Survival Study identified 67 children with a single ventricle from a total live-born cohort of 815 569 children born between 1980 and 1990.[17] This gave a prevalence of 0.08 per 1000 live births and in this study these accounted for 1.37% of all congenital heart disease.[17] The New England Regional Infant Cardiac Program identified 58 infants with single ventricle from 2381 infants with congenital heart disease.[18] These accounted for 2.4% of all congenital heart disease and a prevalence of 0.054 per 1000 live births.[18] Data from the Toronto Hospital for Sick Children revealed that "common ventricle" accounted for 1.65% of all congenital heart defects.[19] O'Leary reviewing the available literature to 2002 suggests a birth incidence of single ventricle of between 4 and 8 per 10 000 live births.[19A] Steinberger and colleagues using data collected from the Baltimore–Washington Infant Study have carried out a population-based epidemiological study of single ventricle.[17A] This survey addressed infants born from 1981 to 1989, finding that single ventricle occurred in 1.25%. Of the 55 patients with single ventricle, the authors interviewed 48 families. Of these 48, 33 had normal situs and 15 had abnormal situs.[17A] Paternal alcohol consumption (OR = 2.0, 95% CI, 1.1–3.9%) and paternal cigarette smoking (OR = 2.4, 95% CI, 1.1–5.1%) were associated with all cases of single ventricle. These associations were even stronger in the subset of infants with abnormal situs. A maternal history of a previous induced abortion was also associated with infants born with abnormal situs (OR = 3.2, 95% CI, 1.1–11.5%). Paternal marijuana use was associated with cases of single ventricle in normal situs (OR = 2.2, 95% CI, 1.0–5.2%).[17A]

A single ventricle malformation has been reported in siblings and in other familial aggregations. In one such report a single ventricle and common arterial trunk were documented in siblings.[20,20A] Weigel and his colleagues have studied the occurrence of congenital heart defects in siblings of patients with univentricular hearts and tricuspid atresia.[21] Eleven of the total 388 siblings (2.8%) of the 189 patients with univentricular heart had a congenital heart defect (see Table 32-1).

Nomenclature

There is still no agreement as to how best to designate those hearts with a functional single ventricle: common ventricle, primitive ventricle, single ventricle, one ventricle hearts, dominant ventricle, univentricular heart, hearts with univentricular atrioventricular connection, double-inlet ventricle, etc. At least some of the difficulty rests with the definition of what is or constitutes a ventricle. Most of us caring for patients with congenital heart disease sort of know what it is when we see it. But the transatlantic discussion regarding nomenclature was quite polarized, at times pejorative, entertaining to a point, and even informative:

Anderson RH, Becker AE, Freedom RM *et al.* Problems in the nomenclature of the univentricular heart. *Herz* 1979; 4: 97–106.[22]

Anderson RH, Becker AE, Tynan M *et al*. The univentricular atrioventricular connection: getting to the root of a thorny problem. *Am J Cardiol* 1982; **54**: 822–8.[23]

Anderson RH, Macartney FJ, Tynan M *et al*. Univentricular atrioventricular connection: the single ventricle trap unsprung. *Pediatr Cardiol* 1983; **4**: 273–80.[24]

Van Praagh R, David I, Van Praagh S. What is a ventricle? The single ventricle trap. *Pediatr Cardiol* 1982; **2**: 79–84.[25]

Lincoln C, Anderson RH. Nomenclatura obscura: subaortic obstruction in double-inlet left ventricle and related lesions. *Ann Thorac Surg* 1991; 52: 730–1.[28]

Anderson RH. Weasel words in paediatric cardiology. *Int J Cardiol* 1983; **2**: 425–9.[29]

Well, I guess you get the idea, the flavor of the discussion and the "players!"

But beyond the obvious differences, the specific types of hearts that we recognize as having a "single ventricle" are important to management and to one's understanding of the natural and modified history. Most agree that the three morphological types of single ventricle hearts include (Fig. 32-1):

- left ventricle type with/without rudimentary right ventricle
- right ventricle type with/without rudimentary left ventricle
- indeterminate or undifferentiated type.

One can construct a complex matrix of the various types of these hearts according to the following morphological variables:

- atrial situs (solitus, inversus, indeterminate)
- type of atrioventricular connection (double-inlet, absent right or absent left)
- right or left hand pattern of ventricular organization
- ventriculoarterial connection (concordant, discordant, double-outlet, single-outlet aorta, single-outlet pulmonary trunk, common arterial trunk).

The concept of a univentricular atrioventricular connection and the 50% rule has certainly added even more complexity to this already complex situation.[30–33] Some hearts with important straddling of the atrioventricular valves, dominant forms, right or left, of the atrioventricular septal defect, hearts with twisted atrioventricular connection, etc., may be best treated with univentricular palliation rather than a high risk biventricular repair (Table 32-2).[34]

One might argue that under the "umbrella" of the 50% rule and the concept of the univentricular atrioventricular connection that some of these hearts belong to the family of single ventricle. Yet there are still some unequivocally biventricular hearts best and perhaps only amenable to univentricular palliation.[35,36] Among these are many forms of hypoplastic left heart syndrome, with aortic atresia or critical stenosis, severe mitral stenosis and a diminutive left ventricle; pulmonary atresia, intact ventricular septum, and a right ventricular-dependent coronary circulation; extreme Ebstein's anomaly for malformation of the tricuspid valve in the newborn with/without organic pulmonary atresia. In addition some forms of double-outlet right ventricle with a remote ventricular septal defect; hearts with an imperforate tricuspid valve with congenitally absent pulmonary valve, etc., are all better treated on the algorithm of univentricular palliation.[35–39] From a variety of studies carried out in the West, a uni-

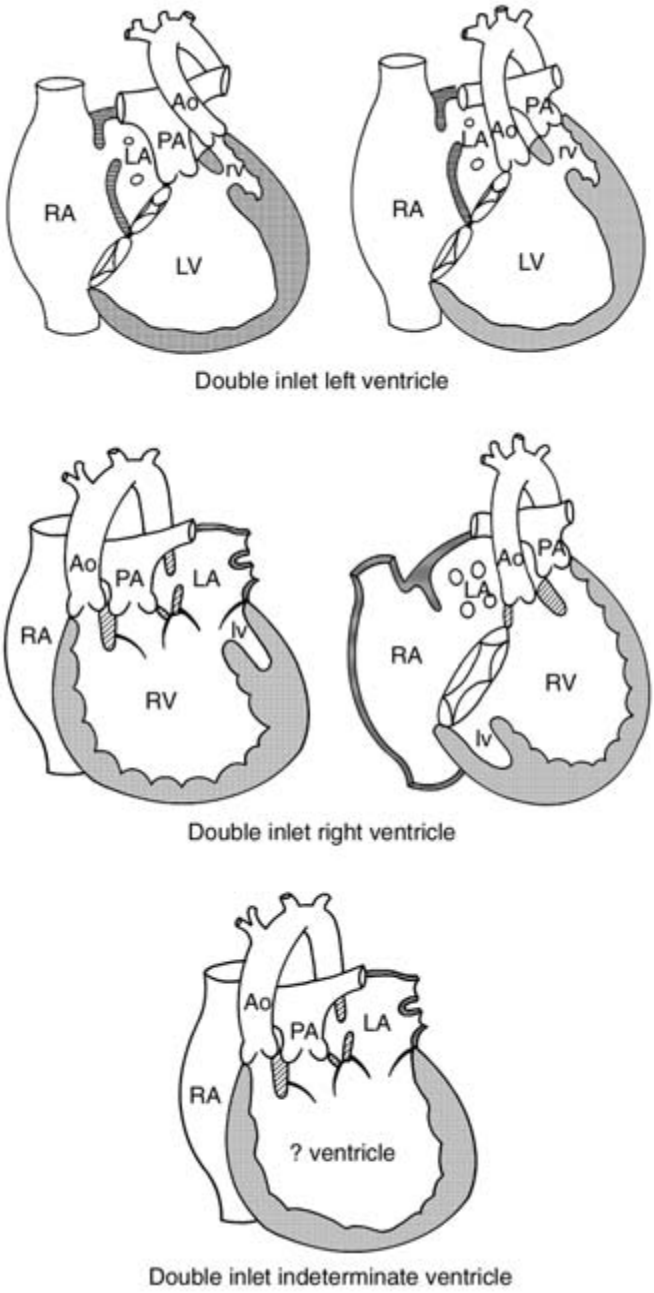

Fig. 32-1 Various forms of double-inlet ventricles in situs solitus. Ao, aorta; LA, left atrium; LV or lv, left ventricle; PA, pulmonary artery; RA, right atrium; RV or rv, right ventricle.

Table 32-1 Occurrence of congenital heart defect in siblings of patients with ventricular heart or tricuspid atresia

Type of univentricular heart	DILV	Complex UVH	Complex UVH and asplenia	Complex UVH and polysplenia
No. of patients	102	69	14	4
No. of siblings in each group	202	140	29	7
No. of siblings with CHD	1	7	1	2
Siblings with CHD (%)	0.5	5.0	3.4	28.6

CHD, congenital heart defects; DILV, double-inlet left ventricle; UVH, complex univentricular heart.

Table 32-2 Conditions requiring univentricular palliation, so-called functionally single ventricles

Double-inlet ventricles
Tricuspid atresia with absent right atrioventricular connections or imperforate tricuspid valve
Other forms of absent right or left atrioventricular connections
Important straddling of an atrioventricular valve or valves
Significantly unbalanced forms of atrioventricular septal defect
Twisted atrioventricular connections with a straddling atrioventricular valve or significant hypoplasia of a ventricle
Hypoplastic left heart syndrome
Most cases of aortic atresia or critical stenosis
Severe mitral stenosis with diminutive left ventricle
Pulmonary atresia with intact ventricular septum, significantly hypoplastic right ventricle, and/or right ventricular-dependent coronary circulation
Extreme form of Ebstein's anomaly of the tricuspid valve with functional or anatomical pulmonary atresia
Double outlet right ventricle with a remote ventricular septal defect that cannot be routed to a ventricular outlet

ventricular atrioventricular connection of left ventricular type is found in 60–70% of patients.[2,8,22,23,30,31,33,40–49] In any of these studies, again in an occidental patient population, the single right ventricle is considerably less common, ranging from *c.* 5% to 25% of cases, and those with an indeterminate ventricle usually < 5%. In an angiographic study of ventricular morphology from the Mayo Clinic published by Julsud and colleagues, the ventricular morphology was determined in 476 patients undergoing a Fontan procedure.[50,51] A dominant left ventricle was identified in 72%, a dominant right ventricle in 16%, and a ventricle of indeterminate morphology in 1%.[51] In an autopsy study of 205 hearts with a double-inlet ventricle, Anderson and his colleagues found double-inlet left ventricle in 140 (56%), double-inlet right ventricle in 25 (12.2%), and double-inlet indeterminate ventricle in 40 (19.5%).[30,52] The incidence of double-inlet indeterminate ventricle in this compilation is considerably higher than most other surveys conducted in an occidental population. Van Praagh and his colleagues found of 31 autopsied cases of single ventricle 23 had a single left ventricle (74.2%) and 8 (25.8%) had a single right ventricle.[41] Wang and coworkers have reviewed the ventricular morphology as determined by echocardiography in 60 Chinese patients with double-inlet ventricle.[53] Interestingly, they found both atria connected to a dominant right ventricle in 36 patients (60%), to a dominant left ventricle in 17 (28%), and to an indeterminate ventricle in 7 (12%).[53] Right isomerism was identified in 30 patients (83%) with double-inlet right ventricle; in 5 (29%) with double-inlet left ventricle and in 86% with double-inlet indeterminate ventricle.[53] Wang attributed the high incidence of double-inlet right ventricle in this study to the high prevalence of right atrial isomerism in the Chinese population and the known association between right isomerism and double-inlet or common-inlet right ventricle.[54,55]

Morphological considerations

At least 60–70% of all univentricular hearts are characterized morphologically by a dominant ventricle of left ventricular morphology.[2,8,22,23,30,31,33,40–49] There is usually a rudimentary right ventricle and the site of communication between these two chambers is a ventricular septal defect, called by some a bulboventricular foramen or outlet foramen (Figs 32-1 upper panel, 32-2).[27,28] The rudimentary right ventricle may be right-sided and anterior or left-sided and anterior.[47] All patterns of ventriculoarterial connection have been observed, but the most common is that of transposition of the great arteries or ven-

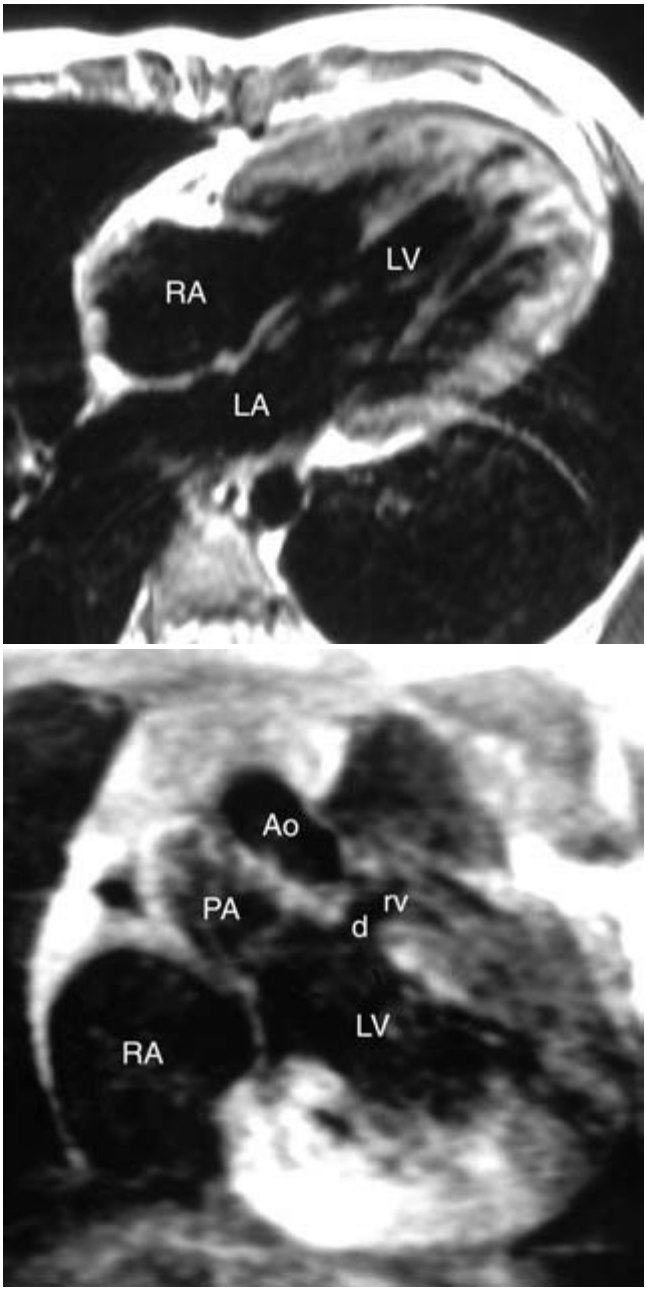

Fig. 32-2 Double-inlet left ventricle of left-hand topology with discordant ventriculoarterial connection. **A**. Axial MR image shows both right atrium (RA) and left atrium (LA) connected to the left ventricle (LV). **B**. Coronal MR image demonstrates the rudimentary right ventricle (rv) located at the superior and left corner of the left ventricle. The ventricular septal defect (d), which is a part of the subaortic outflow tract, is very restrictive. Ao, ascending aorta; PA, pulmonary artery.

triculoarterial discordance.[2,8,22,23,30,31,33,40–49] The most common pattern of internal organization of the ventricle conforms to a left-hand pattern, documented in from 60% to 70% of those with a dominant left ventricle.[2,8,22,23,30,31,33,40–49] The double-inlet left ventricle with left-sided rudimentary right ventricle and concordant ventriculoarterial connections is uncommon, and abnormalities of the left-sided atrioventricular valve are frequent in this setting.[56,57] The Holmes heart with a right-sided rudimentary right ventricle and normal ventriculoarterial connections is more common.[57–61] The second most frequent form of single ventricle is one of right ventricular morphology (Figs 32-1 middle panel, 32-2). A rudimentary left ventricle is usually present along the inferior, posterior or diaphragmatic surface of the ventricular segment. In its "purest" form, a rudimentary left ventricle is absent.[25,26] The single right ventricle is seen most commonly, but not exclusively, in patients with visceroatrial heterotaxy, particularly those with asplenia/right isomerism[53–55] (Fig. 32-3). The least common form of single ventricle is a ventricle of indeterminate morphology (Fig. 32-1 lower panel).[2,30–33,41,45,50,51] The type of atrioventricular connection may be that of a double-inlet, absent right or absent left atrioventricular connection. Virtually any abnormality of the systemic or pulmonary veins, atrial septum or atrial appendage (juxtaposition), form and function of the atrioventricular valves, pulmonary artery, aortic arch (laterality and/or obstruction), etc., may complicate the situation.

Change in form and function of hearts with one dominant ventricle

The change in form and function of "one ventricle" hearts has fascinated many of us for a long time. Any number of studies have addressed the changing nature of hearts with a univentricular atrioventricular connection.[62–79] These phenomena are of course applicable to hearts with a double-inlet or an absent right or absent left atrioventricular connection as well. Indeed, there is probably more information about progressive pulmonary outflow tract obstruction in patients with classic tricuspid atresia and concordant ventriculoarterial connections, and conversely there is more information about the development of systemic outflow tract obstruction in those patients whose aorta originates from a rudimentary right ventricle and pulmonary artery from the dominant left ventricle. Furthermore, hearts with an absent left atrioventricular connection or an obstructive one with an atrial septum that is intact or nearly so, are more likely to be candidates for the development of left atrial hypertension, and the deleterious consequence on pulmonary vascular morphology and hemodynamics. These changing phenomenon include:

- progressive systemic outflow tract obstruction
- progressive change in ventricular function/hypertrophy
- progressive atrioventricular valve regurgitation
- progressive left atrial hypertension
- progressive pulmonary outflow tract obstruction
- progressive deterioration in atrioventricular conduction
- development of pulmonary vascular obstruction
- development of aortopulmonary collateral blood flow.

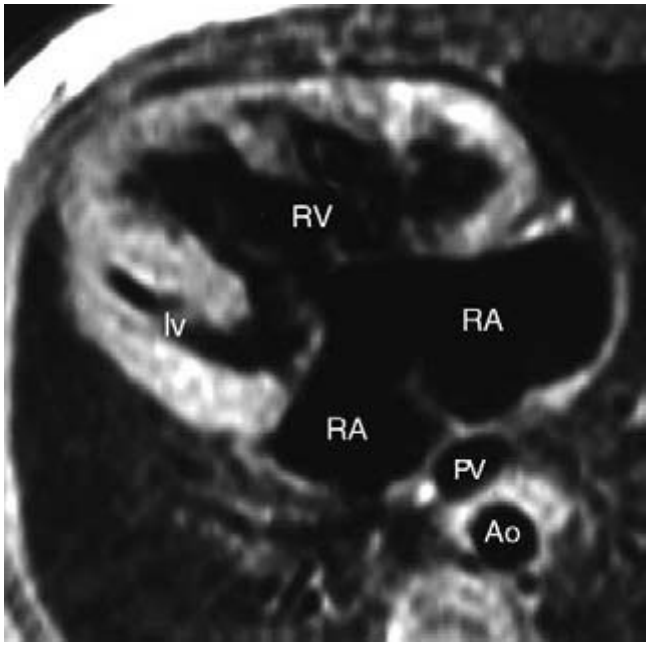

Fig. 32-3 Double-inlet right ventricle in a patient with right isomerism. Axial MR image shows that the whole left-sided right atrium (RA) and more than half of the right-sided right atrium are connected to the anteriorly located main chamber of right ventricular morphology (RV). The rudimentary left ventricle (lv) is located rightward and posterior to the right ventricle. Ao, descending aorta; PV, anomalous pulmonary venous confluence.

Progressive systemic outflow tract obstruction

Systemic outflow tract obstruction has been amply documented in patients with a single ventricle malformation. Subaortic stenosis or atresia may be present at birth, and in some of these patients the systemic circulation is duct-dependent.[45,48,80–88] There is also a substantial literature showing that systemic outflow tract obstruction may be acquired as well.[62,64–66,72,77–79,89–125] The most frequent setting for subaortic stenosis is found in the heart with a univentricular atrioventricular connection of left ventricular type, rudimentary right ventricle and transposition of the great arteries. The aorta originates above the rudimentary right ventricle and blood reaches the aorta and systemic circulation through the bulboventricular foramen or ventricular septal defect. Amongst hearts with a univentricular atrioventricular connection of left ventricular type and a rudimentary right ventricle with a discordant ventriculoarterial connection, the ventricular septal defect tends to be large and neither actually nor potentially restrictive when there is naturally-occurring important pulmonary outflow tract obstruction.[14,47,66,86,96,98,100,111,125] Conversely, in the absence of naturally-occurring pulmonary stenosis, the ventricular septal defect tends to be smaller than the aortic root diameter, and the substrate for subaortic stenosis will be present (Fig. 32-2).[14,47,66,86,96,98,100,111,120,125] These morphological observations should not be surprising considering the reciprocal relationship between systemic and pulmonary blood flow pathways in hearts with complex intracardiac disturbances. There are, of course, exceptions to this reciprocal relationship, and in some patients with naturally-occurring pulmonary outflow tract obstruction subaortic stenosis either will be evident or, over time, will develop. In those patients with a single left ventricle malformation, rudimentary right ventricle, transposed great arteries and an obstructive anomaly of the aortic arch, the ventricular septal defect is likely already restrictive, or certainly smaller than the aortic root, and thus likely to show further reduction in

size.[14,47,66,86,96,98,100,111,125] The patient with a univentricular atrioventricular connection of right ventricular type may also present with or develop subaortic stenosis.[86,125] In this situation the aortic outflow tract is narrowed, similar to the systemic outflow tract in the Taussig–Bing form of double-outlet right ventricle (see Chapter 28). The aortic outflow tract is wedged between the right-sided ventriculoinfundibular fold and the infundibular septum.[86,96,125]

Somerville and her colleagues were the first to report in August 1974 the phenomenon that subaortic stenosis may be acquired in the patient with a "common" ventricle.[64] Both patients reported by these authors had undergone pulmonary artery banding, and before the banding procedure no pressure gradient was measured at cardiac catheterization between the dominant ventricle and the aorta.[64] They wondered whether reduction in size of the bulboventricular foramen was "encouraged" by banding.[64] In 1976 we reported 4 patients who developed subaortic stenosis after pulmonary arterial banding for a "common" ventricle.[65] All 4 patients were found to have a univentricular atrioventricular connection of left ventricular type, a rudimentary right ventricle and transposition of the great arteries. Subaortic stenosis secondary to a restrictive bulboventricular foramen was diagnosed after the pulmonary artery banding. We suggested in 1976 that two factors likely contributed to the development of subaortic stenosis in these patients: (1) the ventricular septal defect or bulboventricular foramen was initially smaller than the aortic root, and thus already predisposed to spontaneous diminution in size; (2) pulmonary artery banding promoted myocardial hypertrophy and this likely contributed to further reduction in size of the ventricular septal defect subsequent to a reduction in pulmonary blood flow.[65] We commented as well that these patients demonstrated at necropsy very severe myocardial hypertrophy that virtually obliterated the functional cavity of the dominant left ventricle.[65] In 1984, we next reported 17 patients with subaortic stenosis complicating a single ventricle malformation.[98] All the patients in this report had a dominant left ventricle, a rudimentary right ventricle and transposed great arteries. In 15 of the 17 patients, the development of subaortic stenosis occurred following pulmonary artery banding, indeed a recurrent theme in these patients. The median duration from the banding procedure until the recognition of subaortic stenosis was 2.3 years. We extended these observations in 1986 by analyzing the courses of 43 patients seen between 1970 and 1985 at the Toronto Hospital for Sick Children with a univentricular heart palliated by pulmonary artery banding.[66] Thirty-two of the 43 patients (74%) had a single left ventricle, a rudimentary right ventricle, and transposed great arteries.[66] For the entire group, subaortic stenosis was diagnosed in 31 patients (72%) after pulmonary artery banding.[66] The mean age at banding was 0.21 years and the mean age at diagnosis of subaortic stenosis was 2.52 years. Rao who has published extensively about the fate of the ventricular septal defect in tricuspid atresia[73,75,76] has written that "it is the intrinsic nature of the ventricular septal defect rather than pulmonary artery banding that is responsible for spontaneous defect closure."[93] Donofrio and her colleagues have offered yet another explanation for the development of subaortic stenosis in these patients.[126] They suggested that early changes in ventricular septal defect size and ventricular geometry in single left ventricle occurs after volume-unloading surgery, namely the bidirectional cavopulmonary shunt. This finding has been confirmed by van Son and his colleagues.[127] This group documented that volume unloading of the single left ventricle resulted in instantaneous contraction of left ventricular size, an increase in left ventricular posterior wall thickness, a decrease of the median bulboventricular foramen area index, and development of a median gradient of 60 mmHg across the bulboventricular foramen.[127] Chin and his colleagues have also demonstrated changes in ventricular geometry and volumes early after the Fontan operation.[128] The views of Donofrio[126] and van Son[127] and their respective colleagues do not exclude the role of pulmonary artery banding as we have proposed in the genesis of subaortic stenosis.[13,14,65,66,96,98,100,125] In fact the views are complementary. Pulmonary artery banding does not result in dramatic instantaneous volume-unloading of the ventricle. But as we wrote some years ago reduction of pulmonary blood flow, myocardial hypertrophy secondary to the pulmonary artery band and increased ventricular afterload, together with the natural predisposition for spontaneous diminution in size of the ventricular septal defect all act in concert to promote systemic outflow tract obstruction.[65,66,86,96,98,100,111,120,125] Although some felt that a pressure gradient between the dominant left ventricle and aorta was necessary to make the diagnosis of systemic outflow tract obstruction, in a number of publications we showed that this was not the case.[66,86,96,98,100,125] The end result of a banded pulmonary trunk and a restrictive ventricular septal defect is relentless myocardial hypertrophy and ischemia.

The ventricular septal defect or bulboventricular foramen is so strategic in these patients as the "guardian" of the systemic outflow tract that it has received considerable attention from the morphologist and from the various imaging modalities. Anderson and his colleagues have shown with clarity the course of the specialized conduction tissue in the double-inlet left ventricle and the so-called safe areas for resection.[102,129,130] We have published extensively on the topography and morphology of the rudimentary right ventricle in the patient with a dominant left ventricle and have documented those sites and the mechanisms that can obstruct the systemic outflow pathway.[47,125] There is less emphasis today on angiocardiographic imaging[86,125,131–138] and more reliance on cross-sectional echocardiographic imaging.[139–141] There has been some interest as well in *en face* imaging or three-dimensional reconstruction of the ventricular septal defect from cross-sectional echocardiography in those univentricular hearts predisposed to subaortic stenosis (Fig. 32-4).[141A,141B,142] Magnetic resonance imaging has also been used in the assessment of the single ventricle through the various stages leading to the Fontan[143–146] and to evaluate Fontan pathway flow dynamics.[138] There is also some data comparing the roles of cross-sectional echocardiography and MR imaging.[147]

Progressive change in ventricular hypertrophy and function

Our early observations about subaortic stenosis did not occur in isolation. There was increasing experience in the late 1970s and into the 1980s with the Fontan operation, various modifications in technique, and expanded indications for this operation. Many examined risk factors for poor outcome of the Fontan operation, forcing continued scrutiny of the original criteria set forth by Choussat and his colleagues.[2,12–16,66,71,72,77–79,89,95–114,116–125] It became apparent that ventricular hypertrophy was identified as a risk factor for poor

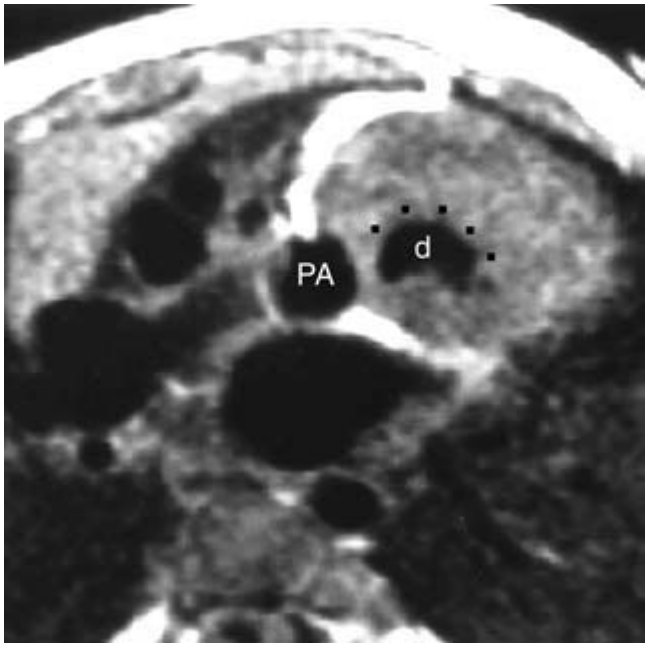

Fig. 32-4 *En face* imaging of the ventricular septal defect in double-inlet left ventricle with discordant ventriculoarterial connection. The cut-through section of the ventricular septal defect demonstrates a cashew-nut shaped defect (d). The expected course of conduction tissue is marked with dotted line. PA, pulmonary artery.

outcome at a Fontan operation, even when all other criteria were met.[2,12–16,66,71,72,77–79,89,95–114,116–125] One of the consistent features in those patients dying at Fontan or requiring early Fontan-takedown was the relationship between pulmonary artery banding and severe myocardial hypertrophy.[13–16,66,71,72,77–79,89,95–114,116–125]

Kirklin and his colleagues in 1986 provided data indicating that ventricular hypertrophy was a risk factor for death after Fontan's operation, and that hypertrophy of the main ventricular chamber may be an inevitable consequence of aging.[118] Seliem and his colleagues addressed in 1989 the relation between preoperative left ventricular mass and outcome of the Fontan procedure for patients with tricuspid atresia.[16] Their data demonstrated that the less satisfactory postoperative clinical outcome may be related to impaired diastolic function associated with inappropriately hypertrophied left ventricular myocardium. Those with a good clinical outcome had a left ventricular muscle mass (g/m^2) of 92 ± 31, while those with a poor outcome had a left ventricular muscle mass of 146 ± 61 (*P* value < 0.001). Thus at least in part the management of the neonate is to avoid those procedures that disproportionately increase the ventricular mass. Data from this institution published by Caspi and his colleagues in 1990 also showed that myocardial hypertrophy contributed to a poor outcome at the Fontan operation.[148] These observations were extended by Akagi in Toronto and Vogel in Munich, both in 1992, and their respective colleagues.[14,15]

The Mayo Clinic has had a very large experience with the Fontan operation. Barber and his colleagues from the Mayo Clinic reported in 1984 the outcomes of their institutional repair of double-inlet left ventricle with obstructed anterior outlet chamber, an experience from 1973 through 1983.[89] Of the 18 patients reported in this paper, 10 patients (56%) died early and there was 1 late death. Thirteen of the 18 patients (72%) had undergone previous pulmonary artery banding. They next reported the results of a staged approach to subaortic stenosis in hearts with a univentricular connection to a dominant left ventricle and an anterior subaortic chamber.[103] Of the 32 patients operated on between 1984 and 1989, the overall mortality decreased to 16%.[103] We reported in 1990 our findings in 37 patients who died from our cohort of 245 patients undergoing the Fontan from 1976 to 1988.[148] During this time our institutional mortality for the Fontan procedure was 15%, but was 40% in those with subaortic stenosis.[148] With increasing awareness of the hazard posed by systemic outflow tract obstruction, many surgical maneuvers were employed to treat subaortic stenosis. These included:

- creation of an aortopulmonary window proximal to the pulmonary artery band*[31,98]
- interposition of a vascular tube graft between the main pulmonary trunk proximal to the pulmonary artery band and descending thoracic aorta*[96,98]
- interposition of an apical left ventricle-to-descending aorta conduit*[98,98A,B]
- arterial switch option with/without pulmonary artery banding*[105,110,149]
- a Norwood (Damus–Kaye–Stansel) operation plus a systemic-to-pulmonary shunt in the neonate and young infant[97,99,109,150–152]
- surgical enlargement of the restrictive vsd plus a bidirectional cavopulmonary shunt[103,114,122]
- Damus–Kaye–Stansel operation plus a bidirectional cavopulmonary shunt[105,106,110]
- arterial switch and modified Fontan*[101]
- Damus–Kaye–Stansel operation plus modified Fontan.[103,114,122,153–155]

Those procedures followed by an asterisk have been abandoned, or nearly so. There is some evidence that there is an advantage to early relief of systemic outflow tract obstruction in univentricular hearts.[104] Ilbawi and his colleagues have shown that early relief of subaortic stenosis (in the neonatal period) is associated with a lower ventricular muscle mass compared to those operated in childhood, and similarly the mass/volume ratio was more favorable in those treated earlier.[104] There is less agreement as to which procedure affords better and sustained palliation at the lowest risk. For the neonate and young infant with obviously severe restriction at the ventricular septal defect, often with an obstructive anomaly of the aortic arch, most would perform a Norwood-like operation with a systemic-to-pulmonary artery shunt, converting to a bidirectional cavopulmonary shunt or hemi-Fontan within the first 6 months or so (Fig. 32-5). While the data about the relationship between pulmonary artery banding, progressive subaortic stenosis and the inevitable consequence of myocardial hypertrophy are compelling, most of these observations were published in the era before routine staging maneuvers to the Fontan were introduced. Indeed, from our many publications, it was often > 2 years from the time of the initial banding procedure to the clinical recognition and diagnosis of subaortic stenosis.[14,66,98,100,111,120] Today many perform the Fontan as early or even earlier than 2 years of age, with staging within the first 4–6 months. Thus there are still some who continue to palliate patients at risk for subaortic stenosis with pulmonary artery banding, acknowledging that these will require early staging with a bidirectional cavopulmonary shunt and either surgical

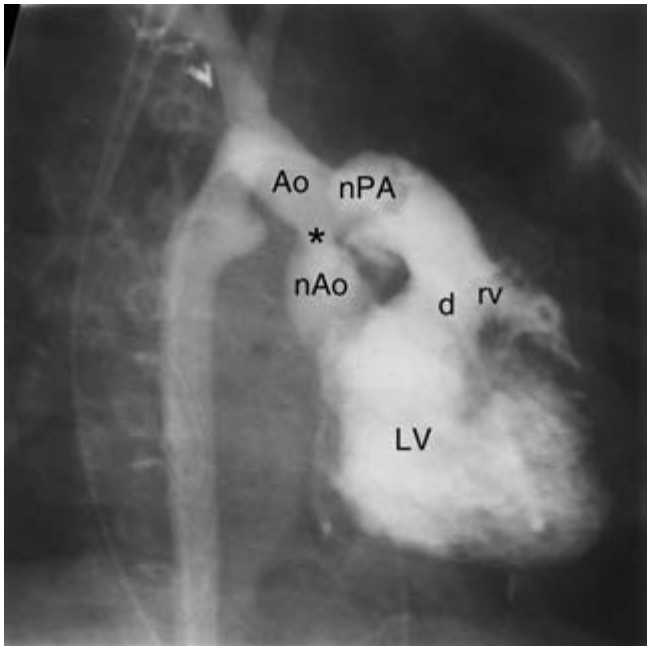

Fig. 32-5 Damus–Kaye–Stansel operation. The patient had double-inlet left ventricle (LV) with concordant ventriculoarterial connection. The native pulmonary artery (nPA) was anastomosed to the aorta (Ao). The native aorta (nAo) developed mild stenosis (asterisk). d, ventricular septal defect; rv, right ventricle.

enlargement of the ventricular septal defect, or a Damus–Kaye–Stansel pulmonary-to-ascending aortic anastomosis (Fig. 32-5).[107,121,123,124,156] When subaortic stenosis is recognized late (i.e. when Fontan surgery is contemplated), a Damus–Fontan procedure can be carried out or the ventricular septal defect can be enlarged at the time of the modified Fontan procedure. Indeed, a Damus–Kaye–Stansel procedure has been performed for systemic outflow tract obstruction recognized after a modified Fontan procedure had been performed,[157,158] although most have tended to enlarge a restrictive ventricular septal defect.[159–161] A number of studies have addressed the fate of the pulmonary valve in the systemic circulation (see Chapters 25B and 31). The most common conditions for the pulmonary valve to function in the systemic circulation are the arterial switch operation for transposition of the great arteries and the Norwood–Fontan continuum for the hypoplastic left heart syndrome.[162,163] Long-term banding of the pulmonary trunk, especially when the band is quite close to the pulmonary valve can lead to morphological changes in the pulmonary valve and pulmonary regurgitation.[164] There are clinical observations indicating that neonatal pulmonary artery banding with subsequent conversion to a Damus–Kaye–Stansel and either a bidirectional cavopulmonary shunt or modified Fontan within a year does not importantly compromise the function of the pulmonary valve.[165,166] Clearly we continue to urge caution[100] in the application of pulmonary artery banding in the treatment of these patients as do others.[116,117,117A]

Some years ago there seemed to be some enthusiasm for the arterial switch option in these patients.[110,149,167–169] However, it was often difficult to control the amount of the pulmonary blood flow, which despite a restrictive ventricular septal defect, tended to be excessive. A number of patients who underwent a palliative arterial switch operation required pulmonary artery banding. Some after the palliative switch became too hypoxic, and required a shunt to augment pulmonary blood flow. We only infrequently used this approach and with our improving results with a Norwood strategy have used the Norwood option with a systemic-to-pulmonary artery shunt.[170] From a survey of the contemporary literature, there seems to be less interest now in the palliative arterial switch option than a decade ago.[170] The assessment of ventricular function in patients considered for Fontan surgery and those factors influencing contractility are discussed in Chapter 36. In the history of the surgical treatment of systemic outflow tract obstruction in the patient with a "single" ventricle, Yacoub and hs colleagues were amongst the earliest, if in fact not the earliest to use a proximal pulmonary artery–aortic anastomosis as palliation.[154] His publication in 1976 overlapped with those of Damus and Kaye and Stansel in 1975, although Damus had conceived of the operation in 1972.[154A] It seems that none of these authors was aware of the others' contributions (see also Chapter 25B).

Progressive atrioventricular valve regurgitation

It is not uncommon for patients with single ventricle morphology to develop progressively severe atrioventricular valve regurgitation.[54,171–178] Considerable scrutiny has been paid to the form and function of the atrioventricular valve(s) in patients with a functional single ventricle. Regurgitation has its basis in both anatomical and functional issues. This occurrence is not ventricular-type specific, but is perhaps more common in those patients with a single right ventricle and a common atrioventricular valve.[54] This association is particularly frequent in patients with right isomerism (see Chapter 33).[179] Some years ago we reported the natural and modified history of 76 patients with a common atrioventricular valve guarding a double-inlet atrioventricular connection, and the dominant ventricle was of right ventricular morphology in 42. Abnormal atrioventricular valve function was detected in 46% of the patients at the time of initial presentation.[54] In this series from Toronto patients with a double-inlet ventricle guarded by a common atrioventricular valve had a high early mortality with 37% dying in the neonatal period.[54] Kawahira and colleagues from the National Cardiovascular Center in Osaka found in their study that of 31 patients with a double-inlet right ventricle, right isomerism was identified in 26% and normal atrial arrangements in 61%.[179] In the 93 patients with a common atrioventricular valve guarding a dominant right ventricle, right isomerism was found in 96% of the patients.[179] Before the Fontan procedure, regurgitation of one or both atrioventricular valves in those with a double-inlet right ventricle occurred in 10%, and in 30% of those with a common-inlet right ventricle.[179] Moak and Gersony have studied progressive atrioventricular valve regurgitation in patients with single ventricle.[172] Of 80 patients with single ventricle reviewed by these authors, 8 developed moderate-to-severe atrioventricular valve regurgitation, and in 7 of the 8 patients ventricular function was preserved. Six of the patients had a common atrioventricular orifice and 2 had an absent left atrioventricular connection.[172] They specifically noted that no patient in this small series had two distinct atrioventricular valves.[172] Ventricular unloading may have a salutary effect on the severity of atrioventricular valve regurgitation.[173] It is unlikely that severe atrioventricular valve regurgitation would be greatly improved solely by the construction of a bidirectional cavopulmonary shunt.[173] Imai and his colleagues have had a

large experience with repair of atrioventricular valve regurgitation at the time of a modified Fontan procedure and have not had to replace the regurgitant atrioventricular valve.[174,175] This experience in conserving the atrioventricular valve differs from that of Mahle and his colleagues who reported the results of atrioventricular valve replacement in 17 patients with single ventricle between January 1984 and August 2000.[176] The types of prosthetic valve included: St Jude's valve in 14, Bjork–Shiley in 1, Hall–Kaster in 1, and Carpentier–Edwards in 1. The valve size ranged from 17 to 33 mm. The median age at valve replacement was 3.0 years (range 7 days to 17.3 years). Of the 16 subjects with normal atrioventricular conduction preoperatively, 7 (44%) developed postoperative complete heart block. The hospital mortality was 29%, but decreased significantly from 56% in 1984–93 to no deaths from 1994 to 2000 ($P = 0.03$). Younger age (< 2 years) at operation was also a risk factor for hospital mortality ($P = 0.03$). There were 4 late deaths in this series and 1 patient underwent heart transplantation. Of the surviving patients, none has required replacement of the prosthetic valve. No patient has had a cerebrovascular accident subsequent to atrioventricular valve replacement. Functional status is New York Heart Association functional class I in 5, class II in 1, and Class III in 1. In this experience, the development of postoperative complete heart block was common.

Progressive left atrial hypertension

Left atrial hypertension is particularly common in those patients with an absent, imperforate, or severely obstructive left atrioventricular valve connection and a restrictive interatrial communication.[180–187] This situation may occur when there is naturally-occurring pulmonary stenosis; or when there is no morphologic substrate for pulmonary stenosis. In the former situation, left atrial hypertension may compromise the function of a surgically created systemic-to-pulmonary artery anastomosis.[184] In those patients with no morphologic substrate for pulmonary outflow tract obstruction, left atrial hypertension and pulmonary venous obstruction may blunt the development of pulmonary vascular obstruction. Indeed, striking changes in a patient's hemodynamics may occur following atrial septectomy (balloon; blade; or surgical). In this regard, while blade septostomy may provide immediate relief of left atrial hypertension, such relief is usually not longstanding.[182] There is no doubt that severe pulmonary venous hypertension, especially when longstanding, impacts on the pulmonary vascular bed. Relief of the obstruction may allow advantageous remodeling of the pulmonary circulation. There is little information in these types of complex malformations as to how long it takes to remodel the pulmonary circulation. The construction of a bidirectional cavopulmonary shunt or Fontan circulation is usually unforgiving if there is any substantial impedance to pulmonary blood flow. Thus it is always wise to delay cavopulmonary surgery for a period of time until vascular remodeling occurs. The development of left atrial hypertension should be anticipated in any patient with severe stenosis or atresia of the systemic atrioventricular valve, and thus sequential assessments of the status of the atrial septum are essential in these patients.[180,182,183]

Progressive pulmonary outflow tract obstruction

When there is the substrate for pulmonary outflow tract obstruction, one should anticipate worsening of the obstruction over time.[188] Thus in the Holmes heart, in patients with tricuspid atresia and concordant ventriculoarterial connections, in any heart malformation with a dominant left ventricle and rudimentary right ventricle and concordant ventriculoarterial connections, there is the potential for pulmonary outflow tract obstruction.[57,62,73–76,125,188,189] The development of pulmonary outflow tract obstruction depends on the initial size of the ventricular septal defect, the nature of the pulmonary valve and infundibulum and whether or not there is true anatomic obstruction of the branch pulmonary arteries. If the ventricular septal defect is initially large and non-restrictive, it is unlikely that diminution in size of the defect will occur and thus spontaneous improvement should not be anticipated. But the morphological bases for pulmonary outflow tract obstruction are diverse and even when the pulmonary trunk originates above the dominant left ventricle, the presence of a subpulmonary infundibulum may provide the substrate for pulmonary outflow tract obstruction. In the patient with a complex cardiac malformation, progressive cyanosis and hypoxemia are not invariably related to progressive pulmonary outflow tract obstruction. It may be related to one or more confounding features including disadvantageous intracardiac streaming especially when there is little mixing at atrial level.[56,125,133,171,190] Progressive left atrial hypertension and/or progressive pulmonary venous obstruction, etc., may also result in worsening hypoxemia. Pulmonary vascular obstruction may also contribute to a deterioration in oxygenation, but this process is slow and insidious. The management of the patient with severe reduction in pulmonary blood flow is to create a surgical systemic-to-pulmonary artery shunt, or less commonly to stent the arterial duct and then perform an early bidirectional cavopulmonary shunt. The pulmonary arteries can easily be distorted by a systemic-to-pulmonary artery anastomosis[191–193] or by ductal constriction.[194–196] Even though the central shunt is rarely used today, some patients may still develop pulmonary artery hypertension secondary to a systemic-to-pulmonary artery shunt.[193] It is important both to maximize mixing at atrial level, thus obviating disadvantageous streaming, and to reduce the potential for left atrial hypertension that the atrial septum be widely open.[171] Thus we favor balloon atrial septostomy in most patients with single ventricle physiology whose atrial septum is actually or potentially restrictive.

Progressive deterioration in atrioventricular conduction

There is only sparse information on the incidence of spontaneous complete heart block in patients with a univentricular heart. As in the patient with double-discordance, one would anticipate a higher incidence of atrioventricular conduction delay in hearts with a dominant left ventricle and rudimentary right ventricle whose internal organization conforms to a left-hand pattern of internal organization. Spontaneous onset complete heart block occurs at a rate of about 2% per year in patients with double discordance.[197–201] Fyler states that *c.* 12% of patients with single ventricle develop complete heart block.[202] Ammash and Warnes reported the survival into adulthood of 13 patients with unoperated single ventricle. Only 1 patient had complete heart block.[203] In the series of 83 patients with unoperated univentricular heart reported by Moodie and his colleagues from the Mayo Clinic, 2 patients presented in complete heart block, but no patient during the period

of follow-up developed complete heart block.[68] These numbers suggest that spontaneous onset of complete heart block is less common in patients with single left ventricle with a left-hand pattern of internal organization than in patients with double-discordance. Alboliras *et al.* reported in 1985 the results of the modified Fontan operation in patients without preoperative sinus rhythm. Of 297 patients undergoing the Fontan operation, 6 had complete heart block, and most had spontaneous preoperative onset of complete heart block.[203A]

Development of pulmonary vascular obstruction

Patients with an unprotected pulmonary vascular bed are at risk to develop pulmonary vascular disease. Such disadvantageous pulmonary vascular remodeling may occur in the first year of life. Many patients with an unprotected pulmonary vascular bed also have an obstructive anomaly of the aortic arch, and this combination is particularly serious, with most such afflicted patients dying in infancy.[48,77] Of the 13 patients with single ventricle surviving into adulthood reported by Ammash and Warnes, 9 had pulmonary stenosis, and 4 had pulmonary artery hypertension.[203] A number of other patients surviving into adulthood have been reported, some with pulmonary artery hypertension and pulmonary vascular obstruction, others with pulmonary stenosis.[204–208] Of 109 adults with Eisenmenger syndrome seen at the University of Toronto Congenital Cardiac Centre for Adults, 11 were found to have univentricular hearts.[209] When patients with complex anatomy are considered (i.e. univentricular hearts, complex transposition, common arterial trunk, etc.), the mean age at death was 28.2 ± 7.9 years. Niwa and colleagues from UCLA studied the outcomes of adult patients with univentricular heart and Eisenmenger syndrome.[210] They identified 16 patients with a univentricular heart ranging in age from 18 to 44 years (mean 30.6 ± 8.4 years). The 5-year actuarial survival rate for patients with a univentricular heart after the initial visit was only 34%. Hemoptysis recurred in 6 patients, and calcification of the pulmonary arterial wall was seen on computerized tomography.[210] During the course of follow-up, 9 patients died at a mean age of 31 ± 6.6 years. Eight of the 9 deceased patients had a univentricular heart of left ventricular morphology, ejection fraction < 30%, moderate to severe pulmonary and atrioventricular valve regurgitation and mild-to-moderate aortic regurgitation.[210] Since the nature of the pulmonary vascular bed is so important to a successful Fontan outcome, there has been obvious interest in the lung biopsy findings and indication for management and outcome.[211–213] Lung biopsy *per se*, once advocated, is now infrequently used in decision-making regarding suitability for the Fontan.[214]

Development of aortopulmonary collateral blood flow

The development of aortopulmonary collateral blood flow has been discussed in several papers[215–219] and elsewhere in this volume (see Chapter 40). Such collateral vessel formation may form in response to previous thoracotomy(ies). Furthermore as shown by Starnes and her colleagues. vascular endothelial growth factor and basic fibroblast growth factor are both increased in children with cyanotic congenital heart disease, possibly suggesting that the widespread formation of collateral vessels is mediated by these growth factors.[220] The incidence of the development, sites of, and various points of connection of systemic venous collateralization are discussed in Chapters 35 and 37.[221–228]

Outcome analysis

The anatomy of a double-inlet left ventricle and other forms of single ventricle pathology lend themselves to fetal echocardiography. The fetal four-chamber view is ideally suited for the recognition of those forms of congenital heart disease where the interventricular septum does not extend to the crux of the heart.[229–231] We have commented elsewhere on the fetal recognition and outcomes of fetuses with tricuspid atresia, hypoplastic left heart syndrome and those complex malformations associated with heterotaxia. Hornberger stated that of the 39 cases in the Allen and Sharland series of double-inlet ventricle, termination of pregnancy took place in 25.[232] There was one intrauterine death and two neonatal deaths, and eleven survived the neonatal period.[232] The prospective Bohemia Survival Study identified 67 children with double-inlet left ventricle.[17] In the first week of life the mean survival curve reached 77.6% and declined until the sixth month of life when the survival rate was 41.8%. The value for the first year of life was 38.8% and at 10 years the average survival curve had dropped to 35.6%, remaining at this level until 15 years of age.[17] Samanek has also reported on the probability of natural survival in patients with single ventricle.[233] Thirty-six per cent survived the first year, and the survival rate at 2 years of age was 33%, dropping slightly at 5 and 10 years to 31%.[233] We commented earlier on the natural survival of patients with double-inlet ventricle to adulthood, most with pulmonary vascular disease and Eisenmenger's syndrome. Survival into the sixth decade without intervention has been reported.[205] Moodie and his colleagues addressed the long-term follow-up of 83 patients with unoperated univentricular heart.[68] This study was already biased as most of the patients were older than 4 years of age.[68] They catalogued the types of univentricular hearts into those with an outlet chamber (type A) or type C, those without an outlet chamber (presumably either a ventricle of right ventricular or indeterminate morphology). For those with type A univentricular heart, 50% were dead 14 years after diagnosis, a death rate of 4.8% per year. By 16 years after diagnosis only 30% were still alive. The outcome for those patients with type C single ventricle was worse, with 50% dead 4 years after diagnosis. The presence of pulmonary stenosis did not seem to affect the overall survival in this series, again clearly biased towards the child. Hager and his colleagues have recently reported on a 62-year-old woman with double-inlet left ventricle, ventriculoarterial discordance and naturally-occuring pulmonary stenosis who at age 59 years developed atrial fibrillation.[68A] A catheter study was performed when she was 62 years and this showed a Qp/Qs of 2.3/1, a mean pulmonary artery pressure of 38 mmHg and the pulmonary vascular resistance was 3 Wood units.m^2. She did not undergo any sugery at that time. This group also tabulated 9 other patients with double-inlet left ventricle and ventriculoarterial discordance surviving from 57 to 62 years of age without surgical intervention. Of the 10 patients including the subject of this report, 6 had native pulmonary outflow tract obstruction, and 4 had pulmonary hypertension and presumably an unprotected pulmonary vascular bed.[68A] Moodie and his colleagues have also reported the long-term follow-up after palliative operations of patients with univentricular hearts.[69] In 1984 they published data on 84 patients aged 6 days to 25 years, mean age 10 years.

The mean follow-up period was 5 years. Of the 84 patients, 33 died and 51 were alive at the time of the report. The survivors were 1.5–41 years, mean 15 years. Using the same classification as in the earlier paper,[69] 5 years after diagnosis 70% of those with type A and 54% of those with type C univentricular heart were alive.[69]

Before the introduction of ventricular septation and then the Fontan operation, patients with single ventricle physiology were candidates for palliation. Palliation took the form of systemic-to-pulmonary artery shunt; pulmonary artery banding with/without repair of an obstructive anomaly of the aortic arch; and/or atrial septostomy/septectomy. Taussig documented in 1976 her long-time observations of the Blalock–Taussig shunt in patients with levocardia and single ventricle.[70] She reported the 20- to 28-year follow-up of 24 patients of the 1037 cyanotic patients operated on between January 1, 1945 and January 1951.[70] Eighteen patients survived the surgery and 1 was lost to follow-up. Eight survived for > 20 years after the initial operation and 6 for > 25 years after the initial operation. Seven patients required a second operation and 4 required a third palliative shunt. Progressive cardiac enlargement was common, indicating both chronic volume loading of the single ventricle and impaired function.[70] Three patients had infective endocarditis and 2 multiple episodes. One patient died with a brain abcess and a second patient died with purulent meningitis.[70] Three women and 4 men married.

Tremeau and colleagues have studied the outcomes of the three main palliative surgical procedures in patients with single ventricle: systemic-to-pulmonary shunt, pulmonary artery banding, repair of the aortic arch (usually associated with pulmonary banding).[234] One hundred and nineteen (63%) of the 185 patients hospitalized between January 1, 1970 and December 12, 1991 in the paediatric cardiology unit of the Cardiac Hospital of Lyon with a diagnosis of single ventricle, underwent one of these three procedures as the initial treatment. The survival of the 22 patients who underwent pulmonary artery banding of 90 ± 6%, 85 ± 8%, 85 ± 8% at 1, 5 and 10 years respectively was significantly better than that of the patients undergoing systemic-to-pulmonary shunt (63 ± 6%, 53 ± 6% and 49 ± 6% at 1, 5 and 10 years, respectively). On the other hand, repair of an obstruction of the aortic arch in the patient with single ventricle physiology had a poor prognosis with survival of only 23 ± 11%, 16 ± 11% and 16 ± 11% and 1, 5 and 10 years, respectively.[234] Dooley and his colleagues reporting the 5-year experience of the New England Regional Infant Cardiac Program stated that 11 of 20 patients (55%) with single ventricle survived pulmonary artery banding.[235] There is little long-term information on the outcomes of patients that have undergone atrial septostomy/septectomy in isolation, although Kirklin and Barratt-Boyes[2] suggest that Redo and his colleagues were likely the first to demonstrate the beneficial effect of a Blalock–Hanlon atrial septectomy in the patient with mitral atresia.[236]

Aeba and coworkers have addressed those factors correlating with outcomes of patients with single ventricle physiology.[237] Between 1961 and 1995, 158 patients with single-ventricle physiology, including tricuspid atresia and hypoplastic left heart syndrome, underwent 260 surgical interventions. The follow-up was 99% complete. The mean (SEM) actuarial survival rates at 1, 5, 10, and 20 years following birth were 70.3 ± 3.6%, 56.3 ± 4.0%, 48.8 ± 4.2%, and 40.9 ± 4.7%, respectively. Definitive palliation was attempted in 38 patients (univentricular in 35 and biventricular in 3). Multivariate analysis identified systemic ventricular outflow tract obstruction, mitral atresia, situs ambiguus, and pulmonary vein drainage tract obstruction as independent prognostic factors for early death. Visceral heterotaxy was the only independent risk factor for lack of application or failure (death or take-down within 30 days of operation) of univentricular or biventricular repair.

Franklin and his colleagues published a series of papers in 1991 addressing the outcomes of patients presenting in infancy with double-inlet ventricle at the Great Ormond Street Hospital for Sick Children.[77–79] The first paper addressed survival without definitive repair;[77] the second paper reported the results of palliative operations;[78] and the third in the series the outcome and potential for definitive repair.[79] This group reported on survival before definitive operation of 191 infants with double-inlet ventricle presenting before 1 year of age from 1973 to 1988, with a median follow-up of 8.5 years.[77] Overall survival including all surgically treated patients was 57% at 1 year, 40% at 5 years, and 35% at 10 years. When the patients were withdrawn (censored) as alive at the time of their definitive operation, the survival rate was 43% at 5 years and 42% at 10 years. Their analysis showed that the hazard rate before the definitive operation decreased dramatically over the first year of life, but persisted at a lower rate throughout the follow-up.[77] A univariate analysis showed that right isomerism, a common atrioventricular orifice, a single-outlet ventriculoarterial connection, obstruction of the systemic outflow at any level, extracardiac anomalous pulmonary venous connections or severe acidosis when first seen were all risk factors for death without definitive surgery.[77] In contrast, the presence of pulmonary valve and/or subpulmonary stenosis and a balanced pulmonary blood flow conveyed a much better outcome. Patients with a double-inlet left ventricle and discordant ventriculoarterial connections with either balanced or low pulmonary blood flow had predicted probabilities of survival of 96% and 90% at 1 year and 91% and 79% at 10 years, respectively.[77] Franklin and his colleagues showed a number of survival curves depicting those with high pulmonary blood flow with/without systemic outflow tract obstruction. For those with a double-inlet left ventricle, discordant ventriculoarterial connections and a high and unobstructed pulmonary blood flow the predicted survival at 1 year and 10 years was 79% and 60%, respectively. The predicted 1-year and 10-year survival for those with unobstructed pulmonary blood flow but also systemic outflow tract obstruction was considerably worse at 36% and 11%, respectively. An even more dismal outlook was found in those patients with right isomerism and double-inlet and double-outlet right ventricle, a common atrioventricular orifice, reduced pulmonary blood flow and extracardiac anomalous pulmonary venous connections, with 1-year and 10-year survivals of 3% and 0%, respectively.

Their second paper addressed the outcomes of 154 palliative operations performed in 121 patients.[78] Survival after either a systemic-to-pulmonary arterial shunt ($n = 57$) or banding of the pulmonary trunk ($n = 35$) was comparable, with 84% and 77% at 1 year, and 62% and 45% at 5 years, respectively.[78] Survival was worse for those who required repair of aortic arch obstruction and pulmonary artery banding ($n = 18$) with survival at 1 and 5 years of 44% and 22%, respectively. Palliative surgery, overall, in this era had a deleterious effect on immediate survival, but in those surviving medium-term outcome was improved, especially for those undergoing a systemic-to-

pulmonary artery shunt. By contrast, after banding of the pulmonary trunk, with or without additional repair of an obstructive anomaly of the aortic arch, medium-term risk was not altered.[78] This lack of benefit was attributed by Franklin and his colleagues to the development of subaortic stenosis in many of these patients, especially those who also required reconstruction of the aortic arch.[78] The third paper addressed outcome and potential for definitive repair of the 191 infants with double-inlet ventricle.[79] They emphasized that management in infancy should be aimed at maintaining the potential for later Fontan surgery.[79] At presentation 136 patients (71%) were potential candidates for a Fontan procedure, but by 2 years of age only 78 patients (57%) were alive and still considered suitable candidates. This attrition was attributed to death after presentation with low cardiac output and at palliative operation. In addition the adverse events of late sudden death and the development of new features precluding a Fontan operation all served to reduce the cohort with potential for the Fontan operation.[79] Patients who required no operation or those requiring only a systemic-to-pulmonary artery shunt fared better than those who required banding of the pulmonary trunk with/without repair of an obstructive anomaly of the aortic arch. Interestingly, they identified only 43 patients from the entire cohort of 191 infants with double-inlet ventricle (23%) who had morphological features additionally compatible with future ventricular septation.[79]

Ventricular septation was the initial method used to partition the single ventricle.[1,2] The surgical history of ventricular septation has been reviewed by Kirklin and Barratt-Boyes.[2] Of the types of single ventricle considered for septation, the double-inlet left ventricle with left-sided rudimentary right ventricle and transposition of the great arteries is seemingly the best candidate as the left atrium, left-sided atrioventricular valve and aorta are all lateralized to the left. Some have surgically partitioned the dominant left ventricle of the Holmes heart as well.[2–8] The form and function of the atrioventricular valves is of paramount importance in ventricular septation. Important atrioventricular valve hypoplasia, straddling of the tension apparatus into the rudimentary right ventricle, crossing or intertwining of chordal apparatus, or sharing of a papillary muscle between both atrioventricular valves could all confound ventricular septation.[1–8,177,178] McKay and her colleagues reported in 1982 the results of septation in 16 patients with univentricular heart of the left ventricular type, two atrioventricular valves, a left anterior subaortic outlet chamber, and transposition of the great arteries.[5] There were 7 hospital deaths (44%; CL 29–60%), 6 from low cardiac output, including each of 5 patients with outlet foramen obstruction. In the subset of 11 patients with unobstructed outlet foramen, there were only 2 deaths, both in patients with small ventricular size. Multivariate analysis in the group of 16 patients indicates that small ventricular size and the presence of outlet foramen obstruction were incremental risk factors for hospital death.[5] In 1984 Ebert reported the outcomes of staged partitioning of single ventricle in 5 patients.[238] The first stage involved the placement of a small patch in the apex and a second patch between the atrioventricular and semilunar valves. A center section was left open, as if there were ventricular septal defect. A pulmonary band was placed at this time if one had not been previously placed. The second stage of the repair, consisting of closure of the ventricular septal defect, was performed 6–18 months after the first procedure. All 5 patients survived staged-partitioning and none sustained complete heart block. One patient subsequently developed pulmonary stenosis, and a right ventricle–pulmonary artery conduit was placed. Naito and colleagues have reported the successful outcome of the staged approach of ventricular septation in a young infant.[239] While this approach did generate some interest,[240] there is relatively little if any more published experience with this approach.

Kurosawa and his colleagues reported in 1990 the results of septation in 12 patients with double- (11 patients) or common inlet (1 patient) left ventricle, left anterior rudimentary right ventricle and transposition.[241] The average age of these patients was 9 years, ranging from 1 to 24 years. Nine of these 12 patients had undergone previous pulmonary artery banding and 1 of these also required repair of a thoracic coarctation.[241] At the time of the septation procedure, 3 patients required enlargement of a restrictive ventricular septal defect. Complete heart block was present in 1 patient before septation and developed in one patient after septation.[241] There was 1 operative death (8.3%). This modest experience did not find a restrictive ventricular septal defect to be an incremental risk factor for death, but did find that an increased left ventricular wall mass portended a poor outcome.[241] Shimazaki and his colleagues and others had earlier suggested that the left ventricular end-diastolic volume of the single left ventricle should be at least 200% of a normal left ventricular end-diastolic volume to achieve a successful septation.[242–244] Four of the 5 patients in Kurosawa's series with a left ventricular end-diastolic volume of the single left ventricle < 200% of normal survived, with the only death in the patient with the smallest volume, 168% of normal.[241] This experience with ventricular septation was extended in 1997 to 23 patients with 2 early (9.5%) and 3 late deaths (14.5%).[245] Non-survivors of ventricular septation were significantly older at the time of operation (14.0 ± 6.0 vs. 7.0 ± 54.4 years; $P < 0.05$). The nonsurvivors also had a greater left ventricular mass (383% ± 100% vs. 206% ± 57% of normal predicted value; $P < 0.005$), and greater left ventricular mass to left ventricular end-diastolic volume ratio (1.84% ± 1.18% vs. 0.77% ± 0.17 of normal predicted value; $P < 0.005$). Univariate logistic regression analysis revealed age at operation ($P < 0.05$) and mass/end-diastolic volume ratio ($P < 0.05$) were significant risk factors for death after septation.[245] The multivariate regression analysis showed that age at operation positively influenced increased mass/end-diastolic volume ratio ($P < 0.001$). Thus as Kirklin *et al.* had suggested earlier in reference to outcome analysis of the Fontan procedure ventricular hypertrophy had a tendency to progress with age[118] and was a risk factor for ventricular septation in Nagashima's *et al.*'s experience.[245] In view of these findings they recommend that if septation is the surgical choice that it be considered early before progression of ventricular hypertrophy;[245] they did not state how early. Although patients with and without pulmonary stenosis have been septated, the better long-term outcomes have been in those patients who have not required a ventricle-to-pulmonary artery conduit.[2,4,5,8,239] The absence of a ventricular-to-pulmonary artery conduit facilitates more functional ventricle and this likely contributes to the better outcome. Margossian and colleagues have recently revisited the issue of ventricular septation, reporting in 2002 their experience with septation of 11 patients with single ventricle.[245A] Eight of the 11 patients survived with 2 early and 1 late death. Six of the patients underwent one-stage septation and 5 planned two-stage. Seven of the 8 survivors have undergone complete septation, 5 as single stage and 2 as two stages. One patient sustained

complete heart block and another patient had significant residual ventricular septal defects.

We will discuss in Chapter 36 the original and modified criteria used to predict a successful outcome for a Fontan-type operation. The Mayo Clinic has provided compelling data that unfavorable early and late outcomes are directly related to the number of preoperative risk factors.[246] The lower the number of risk factors, the better the outcome, and the converse as well.[246,247] Staging to the modified Fontan with a bidirectional cavopulmonary shunt is certainly one factor that has led to improved outcomes of the entire potential Fontan cohort (see Chapter 35). At this staging, one can address surgical or duct-related stenosis of the pulmonary artery, atrioventricular valve regurgitation, and systemic outflow tract obstruction, all factors that can adversely affect the outcome of the modified Fontan operation. There are some data on the repair of the regurgitant atrioventricular valve, and the improvement anticipated by volume unloading surgery.[172–176] Significant atrioventricular valve regurgitation can contribute to ventricular hypertrophy, and thus adversely affect the outcome of the Fontan operation.

The cascade of information about the morphological bases for subaortic stenosis and the surgical maneuvers to deal with this complication have been dealt with earlier in this chapter. Suffice-it-to-say, surgical results to treat subaortic stenosis have continued to improve. There have been numerous reports of the various surgical procedures used to treat subaortic stenosis with/without aortic arch obstruction in the neonate with single ventricle physiology. Although some cardiologists in the 1980s questioned the wisdom of Norwood palliation for the hypoplastic left heart syndrome, Mayer indicated that from this experience we as a "community" have gained considerable experience applicable to many forms of left heart obstructive lesions.[248] Whether one uses a modified Norwood procedure as the initial therapy, the Damus–Kaye–Stansel procedure at the time of staging with a bidirectional cavopulmonary shunt, or ventricular septal defect enlargement, etc., the concern about subaortic stenosis has been largely obviated. Some advocate initial palliation with a modified Norwood approach or Damus–Kaye–Stansel procedure.[151,155,249] Those who use this approach feel there is less re-obstruction of the ventricular septal defect, less heart block, and less damage to the myocardium from the resection of tissue.[151,155,249] However, the use of the Damus–Kaye–Stansel procedure risks distortion of the semilunar valve and increased insufficiency of the semilunar valve.[250] We also reported a higher than anticipated incidence of heart block after the Damus–Kaye–Stansel procedure.[155] Knowledge about the course of the specialized conduction tissue in the double-inlet left ventricle and the so-called safe area for muscular resection has reduced, but not eliminated the risk of surgical complete heart block (Fig. 32-4).[102,129,130,251] In addition, when the incision was made in the rudimentary right ventricle, it was important to avoid disruption of the delimiting coronary arteries.[125,252,253]

Ross and his colleagues reported in 1994 the results of direct relief of the subaortic stenosis in 16 patients with univentricular atrioventricular connection and discordant ventriculoarterial connections.[253] Fifteen of the 16 patients had undergone prior pulmonary artery banding, and 6 had required repair of a coarctation and one patient underwent repair of a type A interruption.[253] All the patients underwent enlargement of the ventricular septal defect via a transventricular approach. There were 4 early and two late deaths, with an actuarial survival of 50% at 7 years.[253] Three of the deaths were related to iatrogenic damage to the aortic valve resulting in severe aortic regurgitation.[253] Two patients sustained complete heart block requiring permanent pacemakers. No patient developed a ventricular aneurysm at the site of the ventriculotomy that was closed with Impra.[253] Pass and his colleagues from the Babies and Children's Hospital of New York reported in 2001 their results of bulboventricular foramen resection in 9 children operated on from June 1990 to June 1999.[254] The patients ranged in age from 1 month to 27 years, with a median age at surgery of 16.5 years. Most of the patients underwent enlargement of the restrictive ventricular septal defect via the aortic root, although several patients also underwent resection via the right atrium and atrioventricular valve.[254] There was one perioperative death in a 3 year old boy who died after bulboventricular foramen resection combined with a Fontan operation. The late death occurred in an infant who underwent a partial septation and bulboventricular foramen resection, dying 5 months after the surgery of fungal sepsis.[254] Brawn and his colleagues reported their experience with a primary Damus procedure for the univentricular heart with systemic outflow tract obstruction.[151] This approach was used in 24 consecutive patients whose median age at operation was 6 days with a median weight of 3.4 kg. They used as well an aortopulmonary shunt 3.5 mm in diameter. There were 9 early deaths (37.5%), and 10 of the 15 survivors had undergone a bidirectional cavopulmonary shunt with one death. One patient required patch angioplasty of the aortic arch and innominate artery with revision of the aortopulmonary shunt. The results of the univariate analysis of the potential risk factors stratified by outcome revealed that presence or absence of transposition, presence of aortic atresia and chronological rank number of the operation were risk factors for death.[151] McElhinney and his colleagues reported in 1997 their approach of a modified Damus–Kaye–Stansel procedure that had been performed in 14 neonates and seven infants with single ventricle and subaortic stenosis, including 15 with arch obstruction.[249] Diagnoses were double-inlet left ventricle (n = 12), tricuspid atresia (n = 2), and other forms of hypoplastic ventricle with subaortic obstruction (n = 7). Three patients underwent concurrent bidirectional Glenn shunt. In the most recent seven patients with arch obstruction, arch repair was achieved with an end-to-side anastomosis of the descending aorta to the ascending aorta with continuous upper body perfusion. One early death occurred among the 14 neonates (7%) and three among the infants, for an early mortality of 19%. At a median follow-up of 33 months, there were no late deaths or neurologic complications. Nine patients underwent subsequent bidirectional Glenn anastomosis, including three who had Fontan completion and one who later underwent conversion to a partial biventricular repair. One patient required a transplant for cardiomyopathy of unknown etiology. The remaining 12 patients were considered good candidates for Fontan completion. No patient has recurrent arch obstruction. Four patients have mild (n = 1) or trivial (n = 3) semilunar valvular regurgitation. They concluded that: the modified Damus–Kaye–Stansel procedure is an effective primary palliation for single ventricle and subaortic stenosis, with or without arch obstruction.[249]

Mosca and his colleagues also using a modified Norwood approach in their initial management of this difficult group of patients have had outstanding results.[152] They reported in 1997 the outcomes in 38 patients with either tricuspid atresia or a double-inlet left ventricle and ventriculoarterial discordance operated between January 1987 and December 1996. The mean

age was 15 days, and their mean weight was 3.4 kg. Aortic arch anomalies were present in 92% of the patients. There were 3 early deaths (7.8%) and 5 late deaths (13.1%). The actuarial survival rates at 1 month, 1 year, and 5 years were 89%, 82%, and 71%, respectively. Follow-up was complete in all children at a mean interval of 30 ± 9 months. None of the patients had significant neoaortic valve insufficiency, and only 1 patient required therapy for residual aortic arch obstruction. Nine patients (30% of the survivors) have undergone the hemi-Fontan procedure, and 18 patients (60%) successfully have undergone the Fontan procedure.

Jensen and his colleagues at the University of California at Los Angeles (UCLA) reported in 1996 the outcomes of pulmonary artery banding in patients with single ventricle at risk for subaortic obstruction.[121] Their patient cohort included 26 patients operated on within 6 months of age between January 1984 and December 1994 at mean age of 2.1 ± 1.8 months. The patients included those with either a double-inlet left ventricle or tricuspid atresia, with transposition of the great arteries in both.[121] Associated aortic arch abnormalities were present in 8 patients (31%). Nineteen patients (73%) underwent further surgery with a Damus–Kaye–Stansel procedure or ventricular septal defect enlargement for a significant subaortic gradient or a morphologically small ventricular septal defect, alone or in conjunction with a bidirectional cavopulmonary shunt or modified Fontan. The cumulative mortality for the entire cohort was 19%. Odim and his colleagues at UCLA continued these observations in 1999, focusing on a staged surgical approach in neonates with aortic obstruction and single ventricle physiology.[124] They reported the outcomes of 15 neonates with single ventricle physiology and either coarctation or interruption of the aortic arch.[124] Again, the surgical strategy was that of initial pulmonary artery banding and repair of the aortic arch obstruction. The median age at operation was 6 days with a median weight of 3.3 kg. There were no early deaths, but 1 late death after the initial palliation. Of the 14 survivors, 8 underwent a bidirectional cavopulmonary anastomosis at a median age of 9.75 months, and 7 infants underwent a Damus–Kaye–Stansel procedure for subaortic stenosis at a median age of 4 months. Thirteen of the 15 patients are alive (87%), and 6 have proceeded to a Fontan procedure. A single failing Fontan required takedown to a bidirectional cavopulmonary anastomosis and central aortopulmonary shunt.[124] Webber and his colleagues have also advocated pulmonary artery banding in the treatment of double-inlet left ventricle with transposition and aortic arch obstruction.[107,123] They reported in 1995 their results with this approach in 17 patients at a median age of 1.4 weeks.[123] Sixteen patients had coarctation and one interruption. Four of the infants had important subaortic stenosis on admission. There was 1 early death after banding and aortic arch reconstruction, and all but 1 developed subaortic stenosis. In these 15, subaortic stenosis was treated with a Damus–Kaye–Stansel operation with 2 early deaths and 1 late death.[123] Of the 13 surviving patients, 12 underwent either a bidirectional cavopulmonary shunt or Fontan. This group uses the approach of pulmonary artery banding and repair of the aortic arch in neonates who do not have severe subaortic stenosis on admission.[123] Lan and colleagues have just reported the results from UCLA of a staged surgical approach to neonates with single left ventricle and moderate size bulboventricular foramen.[124A] This study examined the outcomes of neonates with either double-inlet ventricle or tricuspid atresia with transposed great arteries who had a bulboventricular foramen between 1 and 2 cm^2/m^2. Their institutional results of initial palliation with pulmonary artery banding with/without repair of aortic arch obstruction were excellent and these patients went on to early bidirectional cavopulmonary shunt and a Damus–Kaye–Stansel connection without mortality, similar to the comparison group with an initially larger bulboventricular foramen. These authors did find what they described as a mild bulboventricular foramen gradient (18 ± 10 mmHg) by cardiac catheterization by a mean age of 7 months (before the bidirectional cavopulmonary shunt and Damus–Kaye–Stansel connection). Although the authors state this did not impact on left ventricular wall thickness, since the pulmonary outflow tract remained patent, this gradient is not insignificant.[96,98,100] Daenen and colleagues have also shown gratifying results using a similar staged surgical approach, beginning with banding followed by second-stage palliation at a mean age of 9 months. The cohort consisted of 25 neonates with a univentricular heart, transposed great arteries, subaortic obstruction and pulmonary artery hypertension, with coarctation in 14. The early stages of palliation had no associated mortality.[124B] Furthermore patients from Toronto and the Mayo Clinic who experienced important systemic outflow tract obstruction and ventricular hypertrophy following pulmonary artery banding were treated in a different era and as such the pulmonary artery band was left in place usually for 2 years or longer.[65,66,89,96,98,100,103]

Daebritz and her colleagues from the Children's Hospital in Boston compared the Norwood stage I operation for hypoplastic left heart syndrome and other complex malformations with ductus-dependent systemic circulation.[255] The outcomes of 194 patients undergoing a Norwood stage I palliation between 1990 and 1998 were reviewed. Malformations in 131 patients were classified as hypoplastic left heart syndrome and 63 patients had other lesions. These included hypoplastic left ventricle with ventricular septal defect (n = 18), unbalanced complete atrioventricular canal (n = 9), complex double-outlet right ventricle (n = 14), double-inlet left ventricle (n = 11), tricuspid atresia with transposition of the great arteries (n = 6), and others (n = 5), including heterotaxia. The operative (< 30 days) and 1-year survivals were lower for patients with hypoplastic left heart syndrome than for those with other lesions (63.4% vs. 81%, P = .008, and 51.2% vs. 71.4%, P = 0.02, respectively). The presence of a non-hypoplastic left ventricle (n = 27) was associated with higher operative and 1-year survivals (96.3% vs. 64.7%, P = 0.002; 88.9% vs. 52.7%, P < 0.001). A restrictive atrial septal defect and prematurity tended to increase mortality across both groups. Cox proportional hazards regression indicated that a single right ventricle was the most important independent predictor of death (P < 0.001). Operative mortality for all patients undergoing the stage I procedure decreased from 38.5% (1990–94) to 21.4% after 1994 (P = 0.02). On the basis of these results they concluded that the survival of patients with malformations other than hypoplastic left heart syndrome after the Norwood procedure is better than for those with hypoplastic left heart syndrome. Furthermore, staged palliation is valid surgical therapy in these patients, with good results in intermediate follow-up.[255] Bradley and his colleagues have eschewed pulmonary artery banding in the management of the infant with single ventricle and excessive pulmonary blood flow, rather employing the strategy of pulmonary artery division and a shunt.[255A] From January 1996 to June 2001, 22 patients were operated at a median age of 22 days, with no operative and only

one late death (Fig. 32-6). Thirteen of the 22 patients (59%) had an associated aortic coarctation.

Jahangiri and coworkers reported in 2001 the long-term results of relief of subaortic stenosis in univentricular atrioventricular connection with discordant ventriculoarterial connections.[122] Twenty-four patients underwent enlargement of ventricular septal defect between 1985 and 1998 at a median age of 3.2 years (range 3 weeks to 14 years). Ten patients were younger than 1 year. Eighteen had undergone previous banding of the pulmonary trunk, 9 of whom also required repair of coarctation of the aorta. The median subaortic gradient before enlargement was 46 mmHg. Twenty-three patients had a patch to enlarge the rudimentary right ventricle. Five patients (21%) died in the early postoperative period. The overall survival at 1 and 3 years was 73%, and at 5 and 10 years was 68% and 60%, respectively. Complete heart block requiring insertion of a pacemaker occurred in 2 patients (8%). A Fontan operation was performed in 10 patients, 5 underwent a bidirectional Glenn procedure, and 2 required cardiac transplantation. Follow-up was complete in all survivors at a median time of 6.7 years (range, 8 months to 13 years). From the earlier part of the series, 3 patients experienced aortic insufficiency and 2 had recurrent obstruction. Factors adversely affecting survival were younger than 1 year at operation and presence of obstruction within the aortic arch. Their experience shows that, in patients with univentricular atrioventricular connection to a dominant left ventricle and subaortic stenosis, enlargement of the ventricular septal defect provides satisfactory relief of obstruction except in those younger than 1 year of age, and those who have associated obstruction in the aortic arch. Cerillo and colleagues have also recently reported their satisfactory experience with pulmonary artery banding and enlargement of a restrictive ventricular septal defect.[122A]

We have used during the last three decades a variety of procedures to treat subaortic stenosis in the patient with a univentricular atrioventricular connection.[14,65,66,96,98,100,125,171,256] With our long interest in this condition, we have had a "low threshold" for treating potential subaortic obstruction in these patients at the initial palliative operation, or at the time of staging. Our current initial management of the neonate and young infant with severe systemic outflow tract obstruction has evolved to a Norwood/Damus–Kaye–Stansel approach. In our recent experience, the mortality for the modified stage-one Norwood procedure is in the range of 10%; the second stage had a mortality of 2.5%, with no mortality in the last 60 procedures, and there is a 4% mortality at the time of the modified Fontan procedure.[170] While subaortic stenosis has been and can be dealt with at the time of the modified Fontan procedure, we prefer to deal with it earlier in the surgical algorithm, allowing time for ventricular remodeling and regression of hypertrophy. Systemic outflow tract obstruction can occur after the modified Fontan procedure, tends to progress, and the results for surgical treatment of this post-Fontan subaortic stenosis are good[159–161] (see Chapter 37). It is likely that the substrate for systemic outflow tract obstruction was present before the Fontan and that further ventricular unloading unmasked it.[128] Our own experience with ventricular septation has been very limited, and we have not septated a patient with a univentricular heart in more than two decades. The Mayo Clinic has evolved away from septation,[4] and the University of Alabama has not reported any recent experience with this procedure. Nearly two decades ago, Stefanelli and his colleagues reported the outcomes of the 147 operations carried out in 116 patients with single ventricle between 1967 and July 1982.[257] Confining comments just to the 36 patients who underwent ventricular septation between 1967 and November 1, 1983, 13 (36%) died in the hospital. Of the 13 patients considered to have the ideal morphology for ventricular septation and without the need for atrioventricular valve replacement of a valved extracardiac conduit, there were no hospital deaths and a late survival rate of 77%.[257] In this early experience 88% of the patients at risk for complete heart block did in fact develop complete heart block.[257] The more recent data from Kurosawa and Nagashima and their colleagues from 1990 and 1997 respectively shows less hospital mortality and is thus more encouraging, but compared to the Fontan experience, their numbers of ventricular septation patients are still very small.[241,245] Finally, Cochrane has asked in terms of the management of the univentricular connection: "are we improving?"[258] With one exception we are improving: the management of the patient with a single ventricle and obstructed total anomalous pulmonary venous connections continues to be disappointing.[259–263] Indeed, this may qualify as the "worst disease," not aortic atresia[264] (see also Chapter 33).

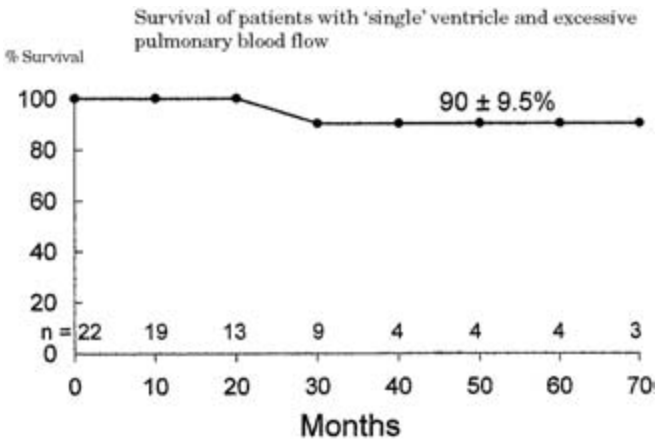

Fig. 32-6 Kaplan–Meier curve depicting survival in a group of infants with single ventricle and excessive pulmonary blood flow treated by pulmonary artery division and a shunt. (From Bradley *et al.*[255A] with permission.)

Double-inlet ventricle issues can be summarized as follows.

- Double-inlet ventricle embraces striking morphological heterogeneity.
- Liveborn prevalence is likely to be reduced by termination of pregnancy.
- The "natural" history is poor without intervention.
- Some particular groups do worse than others including those with isomerism and obstructed total anomalous pulmonary venous connections or those with discordant ventriculoarterial connections and an obstructive anomaly of the aortic arch.
- With the introduction of the Fontan principle in 1968, strategies are employed to protect the integrity of the pulmonary vascular bed and myocardium.
- Patients with double-inlet ventricle and other malformed hearts not amenable to biventricular repair are scrutinized in the context of satisfying the "10 commandments" of Choussat *et al.* to optimize later Fontan outcome.[12]
- Distortions of the pulmonary arteries secondary to an arterial shunt may be addressed at the time of staging maneuvers.

- Myocardial hypertrophy is a risk factor for poor Fontan outcome.
- Systemic outflow obstruction is causal to myocardial hypertrophy.
- Volume unloading surgery, long-standing pulmonary artery banding, and the size of the VSD in patients with double-inlet left ventricle and transposition of the great arteries are important factors in the genesis of systemic outflow tract obstruction.
- Strategies are and must be employed to minimize myocardial hypertrophy acknowledging that numerous factors contribute to systemic outflow tract obstruction:
  - short-term banding followed by staging and intervention to treat systemic outflow tract obstruction;
  - primary palliation with Norwood–Damus type connection.
- There has been some recent interest in ventricular septation.
  - Myocardial hypertrophy is a risk factor for poor outcome of ventricular septation.

The Syndrome of Isomeric Right Atrial Appendages and Visceroatrial Heterotaxy, Often Associated with Congenital Asplenia

It was just half a century ago when Bjorn I. Ivemark, then a young pathologist from Sweden, obtained funding from the Rockefeller Foundation to spend a year at the Children's Hospital in Boston studying a group of very complex cardiac malformations associated with agenesis of the spleen. His wonderful observations about this association were published in 1955 as supplement 104 of Vol. 44 in *Acta Paediatrica*, and his name is deservedly linked forever as "Ivemark's syndrome" with this constellation of anomalies.[1] It was clear from his and others' descriptions of the heart, lungs, and abdominal organs that common to patients with complex congenital heart disease and frequently asplenia was visceral heterotaxy, or abnormal symmetry (Figs 33-1 to 33-3).[2–16] As pointed out by Dr Stella Van Praagh, visceral heterotaxy (from the Greek *heteros*, meaning other, and *taxis*, meaning order) is a syndrome characterized by inconsistency of the situs of the thoracic and abdominal viscera.[15] Often there is preservation of the normal early pattern of liver symmetry and some of the systemic veins.[1–7] Visceral heterotaxy is usually associated with congenital heart disease, pulmonary symmetry, especially bronchial symmetry, splenic abnormalities, including asplenia or polysplenia (although rarely a normal spleen, a bilobed or multilobed spleen, or multiple little splenuli), and some degree of a similar shape of the atrial appendages.[17–21] By convention, some began to characterize these hearts by the nature of the splenic abnormality, referring to patients with congenital heart disease and a splenic abnormality as having the asplenia or polysplenia syndrome. Those features pointing to one or the other syndrome are well-known and have been reviewed in detail elsewhere.[16] As discussed in detail in the subsequent chapter and elsewhere, some prefer to designate these syndromes, not by the nature of the splenic abnormality which may be inconsistent, but rather by the appearance of the atrial appendages, referring rather to the syndromes of right and left isomerism.[22–31] Asplenia tends to occur in those hearts with right isomerism and polysplenia in those hearts with left isomerism. The concept of isomerism in this situation is not precise, but the similarity in appearance of the atrial appendages and the disposition of the pectinate muscles to the atrioventricular orifice suggests bilateral right appendages or bilateral left appendage morphology.[31] Furthermore those who advocate the use of isomerism in this situation state that since one cannot define the atrial anatomy as clearly solitus or inversus, the designation of isomerism, right or left, is appropriate. Some vigorously disagree with this concept, considering it erroneous.[15,28,32] And thus both nosologies are entrenched in the literature. Most patients with visceral heterotaxy have some degree of malrotation with non-fixation as well. The midline symmetrical liver in the patient with cyanotic congenital heart disease was once considered a sign of inoperability because of the often complex cardiac malformations encountered in this syndrome.[4,5,33]

Incidence and patterns of inheritance

The syndromes of right and left atrial isomerism are uncommon in the occidental population. From increasing fetal surveillance and parental counseling, the trend is to a lower liveborn than fetal prevalence. Data from the New England Regional Infant Cardiac Program (NERICP) indicated that 95 of 2251 liveborn infants had congenital heart malformations associated with visceral heterotaxia.[34] More than half of the infants identified by the NERICP with heterotaxy died before their first birthday, and 74% of the babies with levocardia and asplenia or polysplenia died. The Baltimore–Washington Infant Study surveyed 4390 infants with congenital heart disease between 1981 and 1989.[35] Ninety-nine or 2% were identified with heterotaxy, but the breakdown between right and left isomerism was not provided. We identified 91 patients with right atrial isomerism between 1970 and 1996.[36] These accounted for about 2.2% of all the new patients with congenital heart disease seen during that period, about half that of left isomerism. Lin and coworkers identified 58 cases of heterotaxy from a cohort of 201 084 births in the ongoing Active Malformation Surveillance Program at the Brigham and Women's Hospital.[37] Although most cases of heterotaxy in this series were sporadic events, an associated condition was present in about one-fourth of the cases. Not all of these conditions would be considered causative etiologies. Interestingly, three cases were associated with maternal diabetes, but based on this small series alone, maternal insulin-dependent diabetes cannot be viewed as a risk factor for heterotaxy. However, they suggested that the specific association of diabetes with polysplenia with/without left atrial isomerism is noteworthy, and adds weight to animal and epidemiologic case–control data.[38–40]

Ruscazio and his colleagues have reviewed the hereditary patterns of visceral situs abnormalities.[41] From clinical experience, it seems that while most instances of asplenia/right atrial isomerism occur as sporadic events, there are numerous examples of familial occurrence in siblings, suggesting an autosomal recessive pattern of inheritance.[41–48] Furthermore there are a number of sibships with clustering of asplenia and polysplenia syndromes, and one sibship with asplenia in one child and isolated total anomalous pulmonary venous connections in the second child.[48] The familial aggregation of the asplenia and

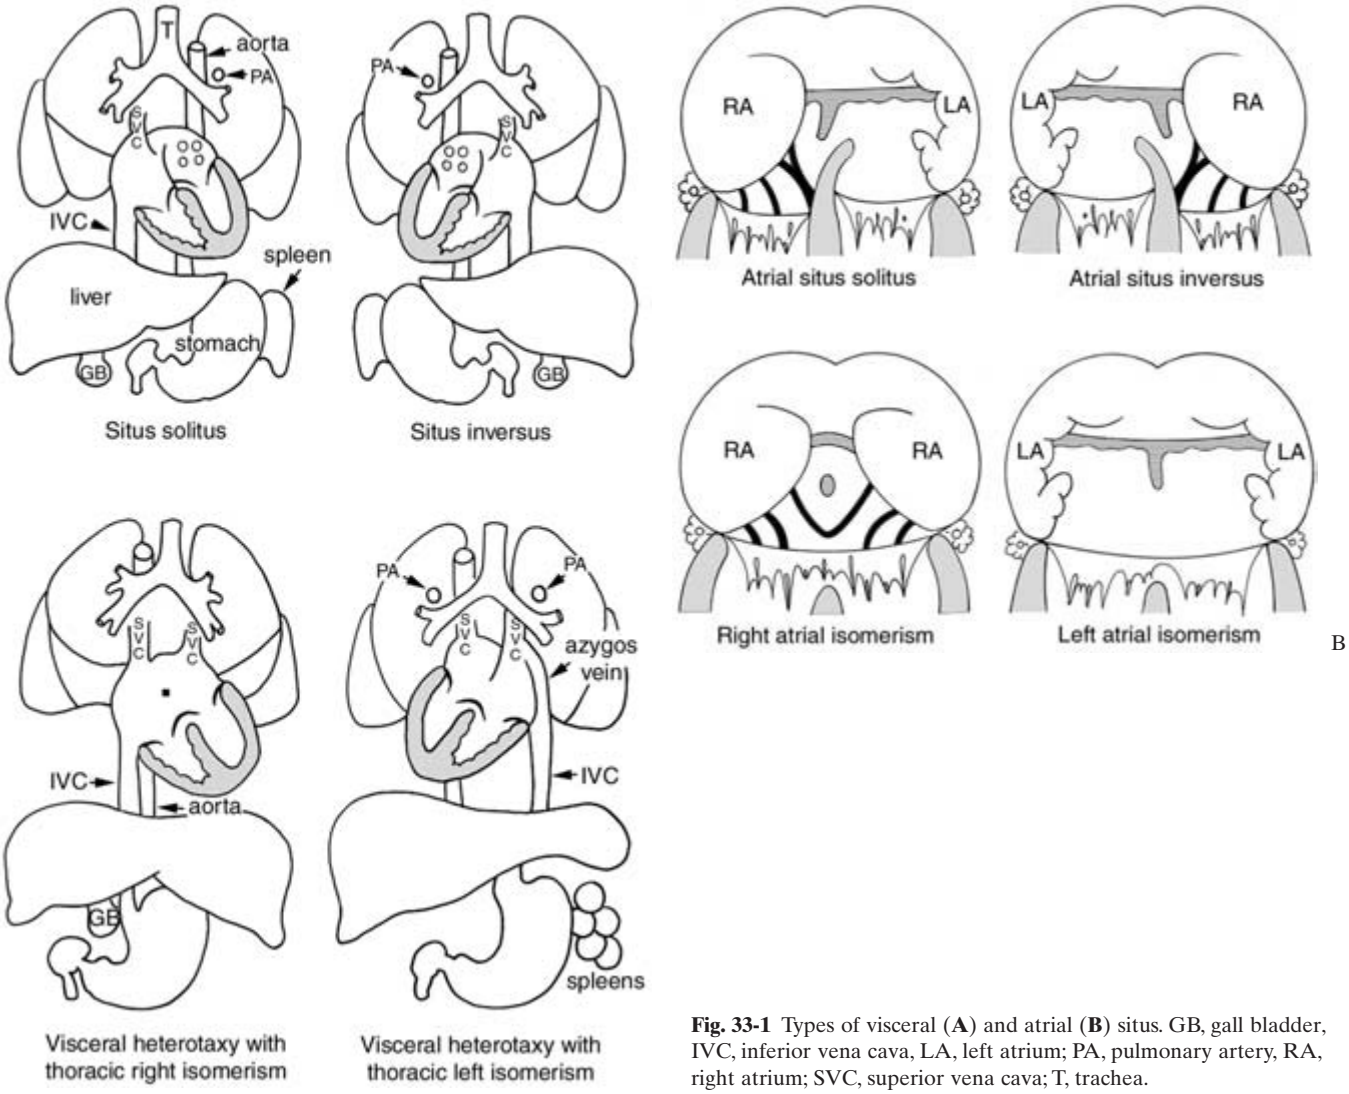

Fig. 33-1 Types of visceral (**A**) and atrial (**B**) situs. GB, gall bladder, IVC, inferior vena cava, LA, left atrium; PA, pulmonary artery, RA, right atrium; SVC, superior vena cava; T, trachea.

polysplenia syndromes in siblings suggests that these syndromes may share common etiologic and morphogenetic factors. Kuehl and Loffredo analyzing data from the Baltimore–Washington Infant study found that a history of maternal diabetes is strongly associated with cardiac disorders of sidedness.[42] Others have found recurrent involvement of chromosome region 6q21 in heterotaxy.[43]

The types of heart malformations identified in patients with right atrial isomerism

The types of congenital heart malformations identified in patients with the right isomerism/asplenia syndrome have received considerable attention since Ivemark's benchmark contribution.[1–3,6–16,19,22,23,26,28,29,31,36,41,49–55] There is considerable overlap of these malformations with patients with left isomerism/polysplenia (Table 33-1).

Indeed, there is not a specific cardiological marker for the patient with right vs. left isomerism. The appearance of the atrial appendages as bilaterally right or bilaterally left and disposition of the pectinate muscles allows one to assign or suggest asplenia and right isomerism or polysplenia and left isomerism.[24,31] But these markers may be difficult to recognize in the clinical situation. In any compilation of hearts with right isomerism, azygos continuation of the inferior vena cava is distinctly uncommon,[15,41] and conversely, probably > 90% of patients with left isomerism tend to have this venous anomaly.[16] Yet an occasional patient with asplenia will have this particular venous anomaly.[41] The abdominal juxtaposition of the aorta and inferior vena cava is highly predictive of visceral heterotaxy and has been acknowledged as typical of patients with asplenia/right isomerism.[56] However, this vascular malposition has been observed in the patient with left isomerism/polysplenia as well.[16]

Hearts with left isomerism tend to be biventricular and those with right isomerism univentricular[57] (see also Chapter 34). Both tend to have complex forms of an atrioventricular septal defect and common atrioventricular orifice. A common atrium is particularly common in patients with asplenia/right isomerism. The ventricular morphology in patients with right isomerism is frequently a univentricular atrioventricular connection of right ventricular morphology. The ventriculoarterial connections in hearts with asplenia/right isomerism are overwhelmingly abnormal, often approaching 90–95%, with double-outlet right ventricle frequently seen, and evidence of bilateral muscular infundibulum.[16,36] The discordant ventriculoarterial connections are distinctly less common than double-

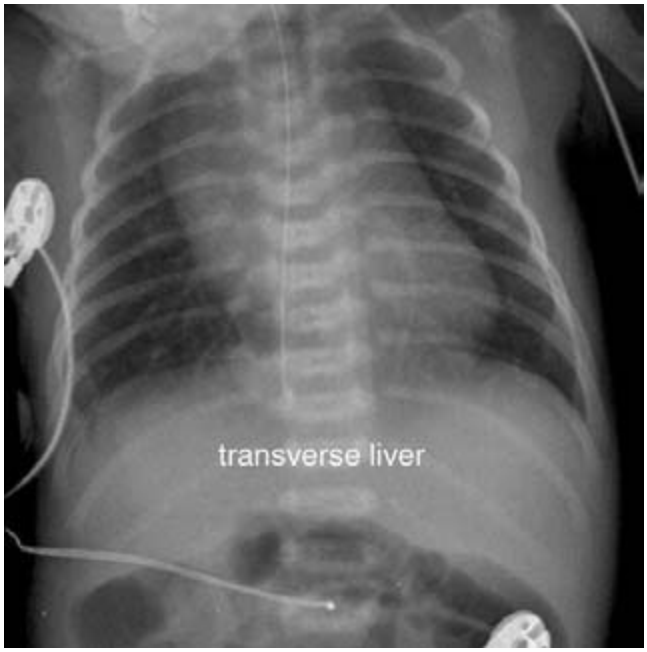

Fig. 33-2 Plain chest radiogram from a patient with right isomerism shows transverse liver.

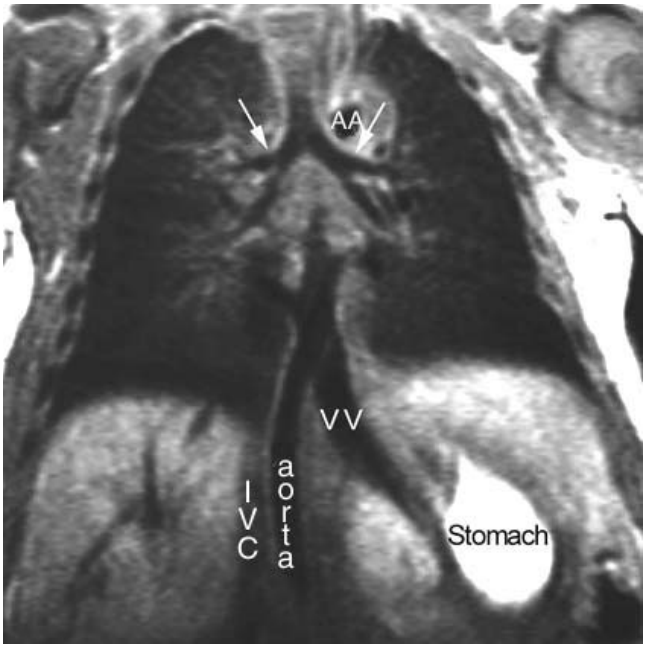

Fig. 33-3 Symmetric bronchial branching in right isomerism. T1-weighted MR image in a coronal plane demonstrates bilaterally short main bronchi (arrows). Neither right nor left pulmonary artery is seen above the bronchi. The aorta and inferior vena cava (IVC) are juxtaposed on the same side of the spine. There is infracardiac type of total anomalous pulmonary venous connection through a vertical vein (VV). AA, aortic arch.

outlet right ventricle in patients with right isomerism. Complex forms of pulmonary stenosis or atresia are very common in patients with right isomerism, although this occurs in the patient with left isomerism as well.[16,36] Systemic ventricular outflow tract obstruction ± coarctation is certainly more common in the patient with left isomerism, but once again, complex forms of aortic atresia have been seen in patients with asplenia/right isomerism.[29,36,53–55] Anomalies of systemic venous connections are common to both groups, especially bilateral superior caval veins. Again from the report of Van Praagh and her colleagues, 71% of patients with asplenia had bilateral superior caval veins, as did nearly half the patients with polysplenia.[15] Nearly 90% of patients with right isomerism have an absent coronary sinus septum with complete unroofing of the coronary sinus. This is less common in the patient with polysplenia/left isomerism.[15] Hepatic vein connection directly to the atrium is particularly common in patients with left isomerism and at one time this finding was considered diagnostic of left isomerism/polysplenia. However, this finding has been noted in an occasional patient

Table 33–1 Common congenital cardiac defects in right and left isomerism

Defect	Right isomerism	Left isomerism
Bilateral superior venae cavae	45%	45%
Bilateral systemic venous drainage	70%	60%
Absence of coronary sinus	~ 100%	~ 60%
Interruption of the inferior vena cava	< 2.5%	80%
Juxtaposition of the aorta and inferior vena cava	~ 90%	Uncommon
Extracardiac type of total anomalous pulmonary venous connection with/without obstruction	50%, with obstruction in 50%	Rare
Pulmonary venous connection to ipsilateral atria	4%	45%
Atrioventricular septal defect	90%	50%
Atrial septum	Functionally common atrium in 50%	Usually better formed, intact in ~ 20%
Atrioventricular connection	Univentricular in 70%	Biventricular in ~ 75%
Ventriculoarterial connection	Concordant only in 4%	Concordant in ~ 70%
Pulmonary atresia or stenosis	80%	30%
Left sided obstructive lesion	< 5%	~ 30%
Heart block/bradycardia	Rare	~ 70%

(From Phoon & Neill,[6] Anderson *et al.*,[19] Hashmi *et al.*,[36] Phoon & Neill,[51] Gilljam *et al.*,[57] Peoples *et al.*[57A] and Uemara *et al.*[57B] with permission.)

with right isomerism, again reflecting the overlap between the isomerism/splenic syndromes.[15] Rarely, an hepatic vein may connect to the coronary sinus or to the left-sided atrium. If this is not recognized before a Fontan procedure and dealt with, then postoperatively these patients may become progressively cyanotic because of hepatic veno-venous shunting (see Chapter 37). Anomalies of pulmonary veins are common in all patients with heterotaxy, but total anomalous pulmonary venous connections, especially with obstruction, occur considerably more frequently in patients with right isomerism.[15,16,36,49–52] In the series reported by Van Praagh and colleagues, nearly two-thirds of patients with asplenia had total anomalous pulmonary venous connections, mostly to a systemic vein (Fig. 33-4).[15] About 60% of patients with polysplenia in their series had normal pulmonary venous connections. Because of the retention of primitive embryonic symmetry in the heterotaxy syndromes, it is not surprising that bilateral sinoatrial nodes have been recognized in patients with asplenia/right isomerism.[9–11]

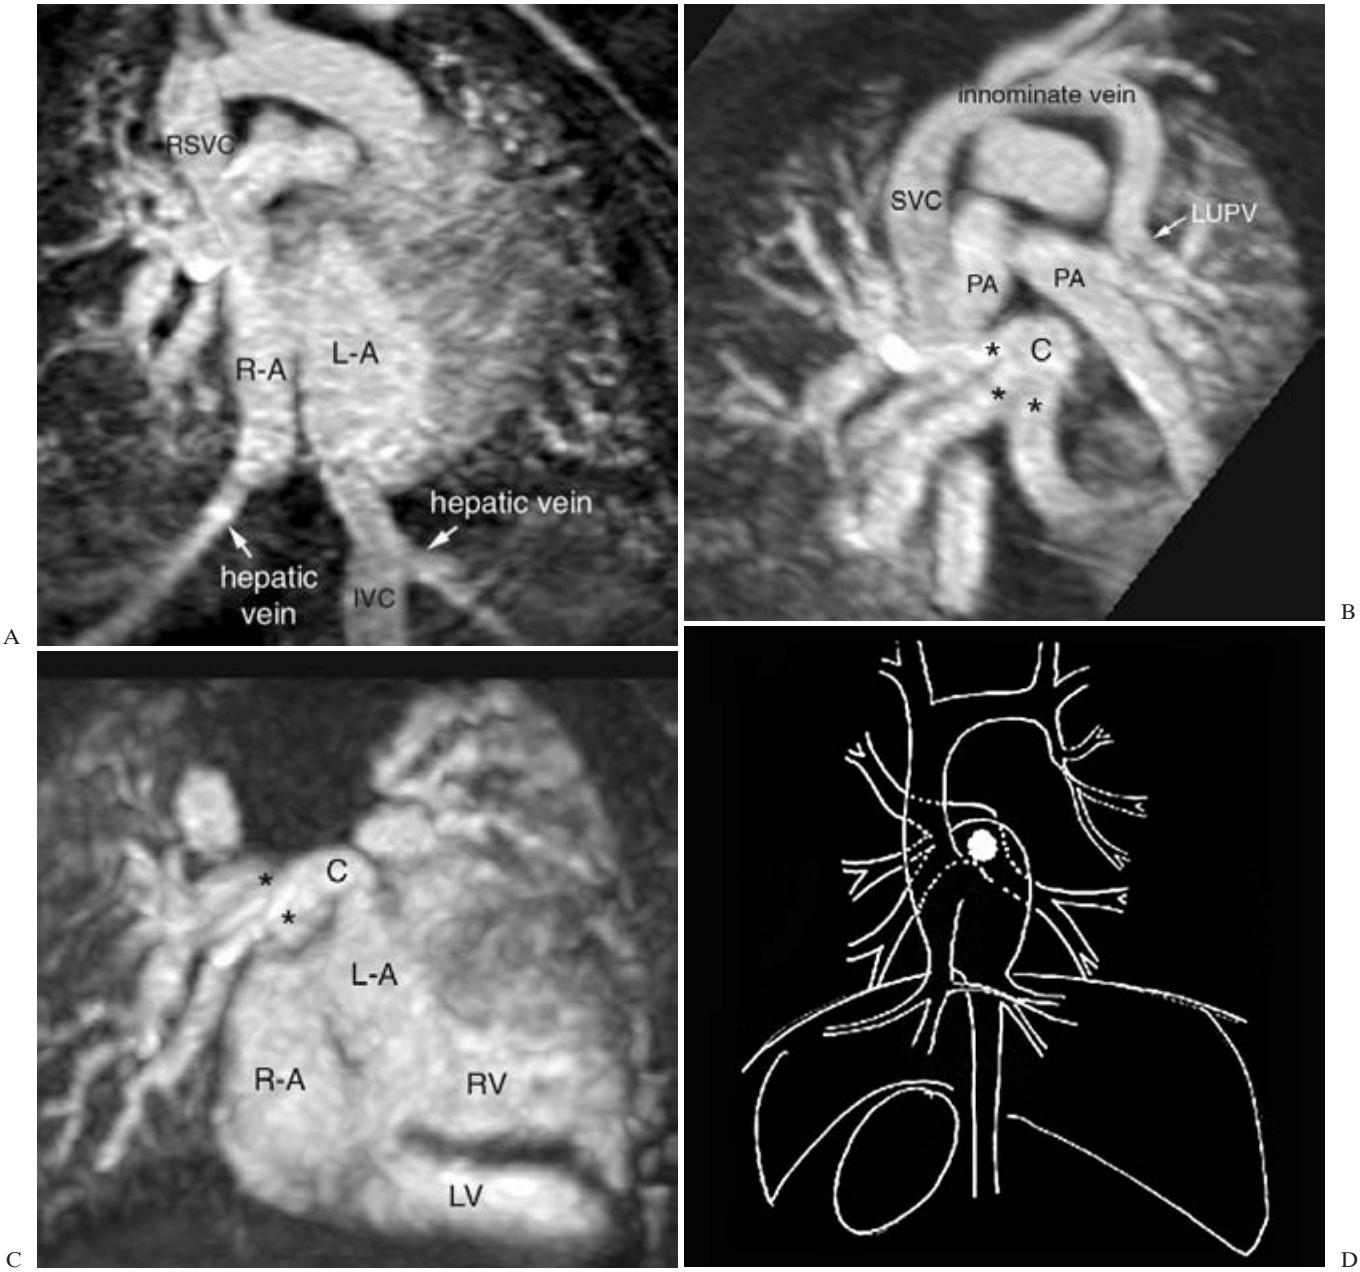

Fig. 33-4 Complex systemic and pulmonary venous anatomy in a patient with right isomerism. Contrast-enhanced MR angiograms show the right superior vena cava (RSVC) and a hepatic vein connected to the right-sided atrium (R-A) and the inferior vena cava (IVC) draining another hepatic vein connected to the left-sided atrium (L-A) (**A**). The pulmonary veins draining the right lung and left lower lung (asterisks) form a narrow confluence (C) to connect to the left-sided atrium (**B**, **C**). The left upper pulmonary vein (LUPV) is connected to the innominate vein (**B**). Composite diagram shown in **D** provided for surgical planning. LV, left ventricle; PA, pulmonary artery; RV, right ventricle. (Reprinted from Valsangiacomo *et al*., Contrast-enhanced MR angiography of pulmonary venous abnormalities in children, *Pediatr Radiol* 2003; **33**: 92–8, Fig. 3, Copyright (2003), with permission from Springer-Verlag.)

The paired sinus nodes and paired atrioventricular nodes are connected by a sling of conduction tissue, thus forming the substrate for an AV re-entrant tachycardia.[9–11,58,59]

Extracardiac abnormalities

Considerable attention has been focused over the years on the extracardiac anomalies in patients with heterotaxy syndromes as these contribute to the morbidity and mortality (Table 33-2).[60–66]

Both groupings have a predisposition to the retention of primitive embryonal symmetry. This is reflected in bronchopulmonary symmetry, hepatic symmetry, non-fixation of the intestines with the potential for malrotation. One of the more common extracardiac feature that most jeopardizes the patient with left isomerism is extrahepatic biliary atresia (see Chapter 34). This complication is extremely uncommon in the patient with right isomerism/asplenia. As we pointed out many years ago and as confirmed by the observations of Phoon and Ticho *et al.*, these patients are at risk for major malformations of gastrointestinal, genitourinary, skeletal, and nervous systems.[6,61] Ticho and his colleagues have stressed the high incidence of midline-associated defects in patients with heterotaxy.[61] These authors suggest that the midline plays an important role in establishing left–right asymmetry. It was also of interest that a midline anomaly was twice as likely to be detected on a complete post-mortem than from clinical observations alone. These findings have been confirmed by others as well.[64]

Patients with asplenia are at risk for overwhelming infection, and thus in any patient with a suggestion of heterotaxy, it is paramount that the presence or absence of a spleen be defined and its function ascertained.[12,21] Any number of investigations have been used in the investigation of splenic status and function, including examination of peripheral blood for Howell–Jolly bodies or pitted erythrocytes, radionuclide splenic scans, ultrasound, magnetic resonance imaging, and abdominal CT scans. Phoon in an exhaustive review of splenic issues in syndromes of isomerism published in 1997 suggests that of all the examinations that have been used in the investigation of splenic status and function, examination of peripheral blood for Howell–Jolly bodies or pitted erythrocytes coupled with ultrasonography is probably the set of tests with the highest sensitivity and convenience.[21] He suggests management of the asplenic patient includes standard and timely immunizations and recommends as well polyvalent pneumococcal and meningococcal vaccines. Daily antimicrobial prophylaxis is also necessary and usually consists of oral penicillin, amoxicillin, or trimethoprim-sulfamethoxazole. This prophylaxis is aimed particularly toward prevention of pneumococcal disease, and is most important in those patients < 2 years of age who have not yet received pneumococcal vaccine. There is not consensus when such prophylaxis can or should be discontinued, and most suggest it be continued into adulthood.

Predisposition to supraventricular tachycardia in patients with right isomerism

The bilateral sinoatrial and atrioventricular nodes which are joined together by a sling of conduction tissue form the ideal substrate for a re-entry type of tachycardia.[9–11,58] Wu and colleagues identified between 1987 and 1996 a total of 101 patients (61 male and 40 female) and 4 fetuses with right isomerism.[59] The median follow-up duration was 38 months, ranging from 0.2 to 270 months. Supraventricular tachycardia was documented in 25 patients (24%) and 1 fetus (25%). The median age at onset was 4 years of age, ranging from prenatal detection to 14 years of age. Actuarial Kaplan–Meier analysis revealed the probability of being free from tachycardia was 67% and 50% at 6 and 10 years, respectively. They found that patients with two ventricles were more likely to develop tachycardia than those with a univentricular heart. The type of ventricular loop, ventricular morphology and position of the cardiac apex were not significant predictors for the occurrence of the supraventricular tachycardia. The tachycardia may compromise the borderline hemodynamics of these patients, especially if they have not undergone complete univentricular palliation. The experience of Wu and colleagues indicates that these patients are good candidates for radiofrequency ablation if they do not respond to medical therapy.[59] Cheung and colleagues have also studied the cardiac rhythm and symptomatic arrhythmias in 110 patients with right isomerism.[59A] They found that all patients but one had normal sinus rhythm with intact atrioventricular connection. Nine-five (87%) had a single P-wave morphology. Fifteen of 85 patients (18%) developed symptomatic cardiac arrhythmias, including 11 with supraventricular tachycardia, 1 patient each with atrial tachycardia, atrial flutter, ventricular tachycardia and congenital complete heart block.[59A] The arrhythmia occurred before surgery in 4 patients, early after surgery in 5 patients and late after surgery in 6 patients. Of the 32 fatalities, in only 1 was it attributable to arrhythmia.[59A] Freedom from arrhythmia at 1, 5, 10, 15, and 20 years was 93%, 86%, 80%, 73%, and 48%, respectively. This group could not identify any risk factor for symptomatic arrhythmia.[59A]

Outcome analysis

There is considerable information about the prenatal diagnosis of patients with asplenia and polysplenia syndrome, using a variety of markers.[67–78] These markers include the association of an atrioventricular septal defect with other complex cardiac

Table 33-2 Extracardiac anomalies in right and left isomerisms

Right isomerism	Left isomerism
Intestinal malrotation virtually in all	Intestinal malrotation virtually in all
Partial thoracic stomach (hiatal hernia) in ~ 25%	Biliary atresia and/or hypoplastic or absent gallbladder in 20%
Very heterogeneous anomalies	Urinary anomalies in 17% encountered
	Duodenal atresia in 7%

(From Van Mierop *et al.*,[11] Hashmi *et al.*,[36] Phoon & Neill,[51] and Gilljam *et al.*[57] with permission.)

malformations, from careful analysis of the spatial relationships between the abdominal aorta and inferior vena cava, non-visualization of the splenic artery, recognition of abnormalities of the fetal central veins and umbilicoportal system, and from recognition of an abnormal right fetal cardiac axis, among others.[67–78] Data provided from a combined experience of 121 cases of isomerism detected during fetal life indicated that left isomerism was detected twice as often as right isomerism.[75] In terms of outcome, 52% of parents elected to interrupt the pregnancy, 10% resulted in a spontaneous intrauterine death, and 13% died after birth. Nineteen per cent of the total were currently surviving. The authors state that the survival rate in continuing pregnancies was 40%.[75] Lin and colleagues recently reported the outcomes of 25 fetuses with right isomerism.[78] Of 25 fetuses with right isomerism, 6 pregnancies were terminated and 10 fetuses were lost to follow-up. Nine patients with right isomerism were delivered, with 5 deaths in infancy.[78]

There is substantial clinical documentation about the poor prognosis in those patients identified with right atrial isomerism.[33,36,51] While prolonged survival has been observed to adulthood in an occasional patient with right isomerism either without surgical intervention or with a shunt only, this is very uncommon.[79,80,80A] Obviously such prolonged survival without surgical intervention requires a balanced circulation. Franklin and his colleagues identified 191 infants with double-inlet ventricle presenting in infancy and studied survival before definitive operations.[81] Thirty-four of these patients had right atrial isomerism, with a 2-year survival of 17 ± 6% and a 5-year survival of 14 ± 6%. The Baltimore–Washington Infant Study identified 71 patients with Ivemark syndrome[35] and Kartagener's syndrome[35] (see Chapter 41E) and they found a 1-year survival of 41%. Unfortunately, the authors provide little specific information about these patients.

A number of reports have detailed the various surgical strategies applied to these patients.[82–104] The majority of patients with right atrial isomerism are candidates only for single ventricle palliation.[36] For some of these patients the results of the various staging maneuvers, the bidirectional cavopulmonary shunt, or Fontan outcomes have clearly improved over the years. In addition, an occasional patient is a candidate for a biventricular repair, often requiring some form of intraventricular tunnel and extracardiac conduit, etc. Biventricular repair has been accomplished in some patients, even those who required unifocalization.[90–92,99] There have been some ingenious procedures to repair/replace a severely regurgitant atrioventricular valve in these patients as well.[92] The common atrioventricular orifice in many of these hearts departs considerably from what is appreciated in standard biventricular hearts, and the observations of Uemura and his colleagues are particularly relevant.[105,106] But most reports of Fontan outcome in patients with right isomerism address the fate only of those undergoing Fontan palliation.[85,94] Fontan results continue to improve in patients with heterotaxy, but most large clinical experiences still show a higher mortality in patients with heterotaxy than those without heterotaxy.[103,104,107,108] We have commented earlier on the prevalence of obstructed total anomalous pulmonary venous connections in patients with right isomerism. There is also some evidence that the pulmonary veins in this condition may be intrinsically small, further confounding surgical management.[49,50,109,110]

The majority of patients with right atrial isomerism have severe reduction in pulmonary blood flow and thus palliation must attempt to augment pulmonary blood flow. A minority of patients will have excessive pulmonary blood flow, and pulmonary artery banding will be required. Unfortunately, in so many of these patients as well, bilaterally obstructed total anomalous pulmonary venous connections complicate the situation and this must be addressed at the time of initial palliation (Fig. 33-2). Defining the adequate amount of pulmonary blood flow has been difficult. Data from several centers indicate that the combination of anomalies (reduced pulmonary blood flow and obstructed pulmonary venous connections) in the neonate conveys a dismal outlook.[36,84,86–88,95,96–98,102] Sadiq and his colleagues have reviewed the experience of the United Kingdom's Birmingham Children's Hospital with the management and outcome of infants and children with right atrial isomerism.[87] They reviewed the outcomes of 20 consecutive children with right atrial isomerism and complex congenital heart disease requiring surgical intervention from 1987 to 1993. The patients were divided into two groups, 11 patients requiring intervention in the first month of life (mean age 5 days), and the remainder who required surgery after the first month of life (mean age 6.8 months). Seven of the 11 patients in the first group had obstructed total anomalous pulmonary venous connections, and 10 of the 11 had pulmonary atresia. There were 7 early deaths including the 5 patients who required both a systemic-to-pulmonary artery shunt and simultaneous repair of obstructed pulmonary veins. The long-term survival in this group was 18%. Amongst the second group, pulmonary venous obstruction was found in 2 patients and 4 had pulmonary atresia. There were no early deaths, with 1 late sudden death and 1 death at a second palliative procedure. The long-term survival rate for this group was 78%. Gaynor and his colleagues have reported on the long-term outcome of 73 infants with single ventricle and total anomalous pulmonary venous connections treated between 1984 and 1997.[95] Overall survival was 45% at 6 months of age, 37% at 1 year of age, and 19% at 5 years. Twelve patients died before surgery. Of the 61 patients undergoing surgery, survival was 54% at 6 months of age, 44% at one year of age, and 23% at 5 years. The heterotaxy syndrome was present in 52 patients. For the entire cohort, survival was worse for those with obstructed total anomalous pulmonary venous connections than for those without obstruction ($P = 0.02$). Like the experience of Sadiq, repair of total anomalous pulmonary venous connection at the time of the initial operation was associated with worse survival ($P = 0.02$). Cheung and colleagues reported on the outcomes of a large cohort of infants with right atrial isomerism, also showing that those with obstructed pulmonary venous connections had a far worse outcome than those with normal connections.[95A] Their review comprised 116 patients seen between January 1980 and December 2000. No interventions were planned in 31 patients (27%), all of whom died. The overall mean survival at 1 month, 1, 5, 10, and 15 years was 80%, 65%, 51%, 43%, and 34%, respectively. The significant independent risk factors for survival were pulmonary venous obstruction and a main ventricular chamber of single ventricle morphology.[95A]

We reviewed several years ago the management and outcomes of all 91 patients with right atrial isomerism seen to that time at the Toronto Hospital for Sick Children from 1970 to 1996.[36] Eighty-nine per cent presented within the first month of life, and 62% at birth. Fifty-four were males (58%) and this is consistent with the male dominance in this syndrome. Cardiac anomalies included a common atrioventricular septal defect in 81%, ventricular hypoplasia or "single" ventricle in 73%, abnormal ventriculoarterial connection in 96%, pulmonary outflow

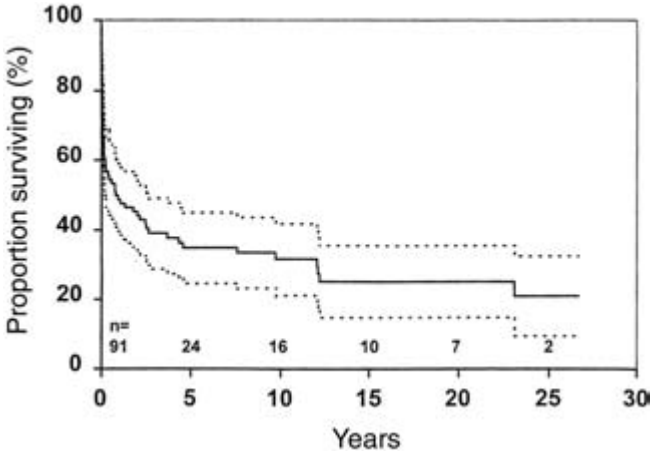

Fig. 33-5 Kaplan–Meier survival estimates of overall survival of 91 patients with right atrial isomerism. The overall mortality was 60%. Dashed lines, 95% CL. (Reprinted from Hashmi, *et al*.,[36] Copyright (1998), with permission from The American College of Cardiology Foundation.)

tract stenosis or atresia in 84%, and anomalous pulmonary venous connections in 87%. The pulmonary venous connections were obstructed in 30%. The overall mortality was 69%. No interventions were planned or performed in 24%, 95% of whom died. The mortality rate for patients requiring their first cardiovascular operation in the neonatal period was 75% vs. 51% for those with later first operations ($P < 0.05$). The surgical mortality for those undergoing pulmonary vein repair ± a systemic-to-pulmonary artery shunt in the first month of life was 95%. Overall estimates of survival were 71% at 1 month, 49% at 1 year, and 35% at 5 years (Fig. 33-5). Independent risk factors for decreased time to death included the absence of pulmonary outflow tract obstruction, presence of severe atrioventricular valve regurgitation, and obstructed pulmonary veins. The majority of the patients were candidates for single-ventricle palliation. However only 22% had completion of their Fontan connection, with a surgical mortality of 21%. Our Fontan mortality was considerably higher for these patients in the earlier era than in the past 10 years, similar to reports from the Mayo Clinic and elsewhere. We have recently reviewed our more recent institutional experience with the outcomes of the Fontan operation in children with atrial isomerism and heterotaxy.[103] Between January 1993 and April 2000, 30 patients underwent a total cavopulmonary connection for atrial isomerism and heterotaxy at a mean age of 5.3 ± 3.6 years. Nineteen had right and 11 left atrial isomerism.[103] There were 4 hospital deaths. Kaplan–Meier survival at 1 month was 86% (95% CL, 75% to 97%) and at 1 and 5 years 83% (95% CL, 70% to 96%). Others have also reported excellent outcomes for small numbers of patients with asplenia syndrome undergoing total cavopulmonary connection [103A,103B] (see also Chapters 35 and 36). Stamm and his colleagues reviewing the Fontan experience of 135 patients with the heterotaxy syndrome (93 with right isomerism and 42 with left isomerism) at the Boston Children's Hospital reported a surgical mortality of 19% before 1991; 3% since 1991 and in this large experience no patient died after 1993.[103B] The "denominator" of this study is unclear, and it would be of interest to know how many patients with heterotaxy died before any surgery was carried out, during or before any staging procedure, and how many were excluded from Fontan surgery. Esophageal varices have been observed in some of these patients, and massive hemorrhage has been seen.[111 112]

Finally, despite the complexity of systemic and pulmonary venous connections in these patients, previous cavopulmonary connection, palliation and dextrocardia, a number of these patients have undergone successful cardiac transplantation.[113–115] Larsen and colleagues have reported the results of cardiac transplantation in 29 patients with visceral heterotaxy.[116] The median age of cardiac transplantation was 3.1 years, and 20 patients had undergone some form of cardiac surgery before cardiac transplantation. The actuarial graft survival at 30 days, 1, 5, and 10 years was 100%, 86%, 68%, and 50% respectively. For those surviving Fontan palliation, one can anticipate a variety of late complications (see Chapter 37). Perhaps particular to this group of patients is the long-term function of the systemic, morphologically right ventricle, and the form and function of the common atrioventricular valve.[117]

The Syndrome of Isomeric Left Atrial Appendages, Often Associated with Polysplenia

In the previous chapter we defined a group of patients in whom it is seemingly difficult, if not impossible, to assign visceral situs because the abdominal viscera are not lateralized, or at least incompletely lateralized[1–13] (see Chapter 33). These patients additionally share in common splenic abnormalities, often complex congenital heart disease, and extracardiac anomalies. In this chapter we will examine those patients who have been identified with so-called left atrial isomerism, acknowledging that many but not all of these particular patients have polysplenia (Figs 34-1 to 31-3). Indeed, polysplenia was the terminology first used to identify and group such patients. It was Moller and his colleagues in 1967 who first fully documented the polysplenia syndrome.[1] Considerable data summarized by Becker and Anderson support their view that cardiac malformations and designation should not be based on the type of splenic malformation because splenic status is often a poor marker of cardiac morphology.[2] This view departs considerably from convention because the terms asplenia and polysplenia have become so entrenched for the designation of certain complex forms of congenital heart disease. Most patients with polysplenia have normal splenic function, but polysplenia carries an impact beyond the functionality of the splenic tissue itself, the potential for splenic torsion,[3–5] the association with extrahepatic biliary atresia,[6–15] malrotation and the short pancreas (see Chapter 33, Table 2).[16–22] Up to 25% of babies with biliary atresia bear associated malformations that most often cluster in the polysplenia syndrome.[8,9] Vazquez and his colleagues found that the anomalies associated with polysplenia/biliary atresia did not jeopardise those surgical maneuvers promoting biliary drainage.[8] Thus while one may infer or suggest the status of the spleen on the basis of the particular constellation of cardiac anomalies, clearly each patient must be evaluated for his or her particular splenic status and cardiac anomaly.[23] What unites patients with asplenia/right isomerism and polysplenia/left isomersim is visceroatrial heterotaxy and congenital heart malformations, usually more severe in the former group (see Chapter 33).

Incidence

Data from the New England Regional Infant Cardiac Program (NERICP) indicated that 95 of 2251 infants had congenital heart malformations associated with visceral heterotaxia.[24] More than half of the infants identified by the NERICP with heterotaxy died before their first birthday, and 74% of the babies with levocardia and asplenia or polysplenia died. Through 1975 at the Toronto Hospital for Sick Children we had recognized 52 patients with asplenia or polysplenia.[26] Thus the prevalence at live birth is very uncommon.[25,27,28] We have extended our observations about asplenia/right isomerism with the publications from Hashmi[29] and Gilljam and colleagues.[30] Over a 28-year period we identified 163 patients with left atrial isomerism at the Toronto Hospital for Sick Children. This population accounted for 0.4% of all new patients seen at our institution over this period.[30]

There are some data addressing the genetics of defects in laterality/atrial isomerism. Clinical data on recurrence of atrial isomerism show that only about 5% of siblings are affected.[31–37] This is considerably lower than the experimental work of Layton and Manasek would suggest.[38] Their data support the concept that situs inversus or ambiguus is due to an autosomal recessive trait with reduced penetrance. Fetal loss could explain some of this discrepancy. Cesko and colleagues have described an autosomal-recessive inherited familial heterotaxy syndrome with two affected siblings – one of whom has situs inversus, and the other with polysplenia syndrome.[35] It is also of interest that there is a tendency for right isomerism to affect males, and for left atrial isomerism to affect females. In our report of left isomerism, 63% were female. These findings indicate that there is an increased risk of inheriting atrial isomerism, and that genetic counseling is indicated after the birth of an affected child. There is also the suggestion that heterotaxia occurs as an outcome of maternal diabetes, but the population on which this hypothesis is based is quite small.[39–42]

The types of heart malformations identified in patients with left atrial isomerism

Anderson and his colleagues[43] have provided a thoughtful summary of the types of heart malformations associated with these syndromes, and provided a comprehensive literature review as well. They state: "The essence of the cardiac malformation is atrial isomerism. This does not mean that the hearts have two normal right atria (each receiving a superior caval vein, an inferior caval vein and coronary sinus) or two normal left atria (each receiving four pulmonary veins). Description of atrial isomerism simply means that there is duplication of those parts of the atrial chambers that exhibit the characteristic anatomical features of rightness or leftness".[43] Van Praagh and his colleagues take those to task for what they consider inappropriate usage of the term "isomerism," furthermore indicating that the atria in such patients are indeed lateralized despite a superficial appearance of atrial symmetry.[44–46]

Any number of studies have catalogued the types of heart

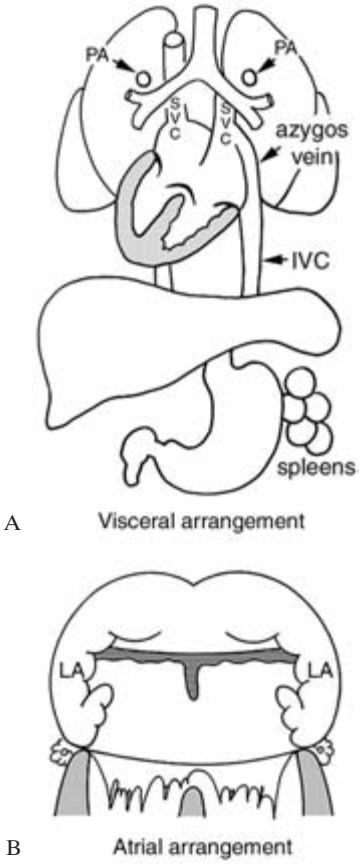

Fig. 34-1 Visceral (**A**) and atrial (**B**) arrangement in left isomerism. Both lungs consist of two lungs with symmetrically long bronchi and the pulmonary arteries (PA) coursing backward above the main bronchi. The liver tends to be symmetrical and multiple spleens are present in most cases. Interruption of the inferior vena cava (IVC) with azygos continuation is common. Both atrial appendages show the morphology of the normal left atrial appendage. The pectinate muscles do not extend to the atrioventricular junction on both sides. SVC, superior vena cava.

malformations associated with the syndromes of disturbed lateralization, atrial isomerism and splenic abnormalities. There is considerable overlap in the complex heart malformations within these two syndromes (see Chapter 33 Table 33-1). Perhaps the most specific marker of the syndrome of left atrial isomerism (aside from bilaterally left atrial appendages) and often polysplenia is azygos continuation of the inferior caval vein (Fig. 34-3), a finding only rarely documented in right isomerism and asplenia.[1,26,37,45–47] Both syndromes demonstrate anomalies of systemic and pulmonary venous connections. Hearts with left atrial isomerism demonstrate a normal ventriculo-arterial junction in almost 70%, according to the extensive institutional review of Gilljam and literature review of Peoples and their colleagues.[30,48] Hearts tended to be overwhelmingly biventricular in hearts with left atrial isomerism, and conversely, among hearts with right atrial isomerism, the atrioventricular connection was univentricular, almost always to a double inlet ventricle via a common atrioventricular orifice. In both syndromes complex forms of atrioventricular septal defect are common. The cardiac apex could be in the left chest, the right, or in the midline. Amongst the patients with polysplenia, normal pulmonary venous connections predominated in the Van Praagh survey, followed by total anomalous pulmonary venous return to the morphologically right atrium.[45] Less common still was drainage of the right pulmonary veins to the right-sided atrium and left pulmonary veins to the left-sided atrium. In their analysis of systemic and pulmonary venous connections in patients with visceral heterotaxy, they found a consistent relationship between the presence of totally anomalous pulmonary venous connection to a systemic vein and an abnormal infundibulum, subaortic or bilateral.[45] Partial or total direct pulmonary venous connections to the right atrium has been attributed by Van Praagh and her colleagues to malposition of septum primum.[49] Of the 36 patients reported by these authors, 33 had visceroatrial heterotaxia.[49] Jenkins and her colleagues have found that individual pulmonary vein size at diagnosis is a strong independent predictor of survival in patients with totally anomalous pulmonary venous connections.[53] The outlook for surgery for patients with single ventricle pathology, pulmonary outflow tract obstruction and total anomalous pulmonary venous connections has been poor[29,50–52] (see also Chapter 37). The poor results have been attributed in part to defective development of the pulmonary veins.[53–55] Although this consideration is more germane for the patient with right atrial isomerism, these considerations will be important for some patients with left atrial isomerism.

Complex forms of atrioventricular septal defect are common to both syndromes, but systemic outflow tract obstruction is certainly more common in those patients with left atrial isomerism.[55A] Complex forms of pulmonary atresia are also seen in both syndromes, but these are more common in the group of patients with right isomerism. While for > 40 years we have been aware of azygos continuation of the inferior caval vein,[56] we have more recently documented the so-called persistent primitive hepatic venous plexus with underdevelopment of the infrahepatic inferior vena cava in patients with left atrial isomerism.[57–59] Rarely, the hepatic vein may connect to the coro-

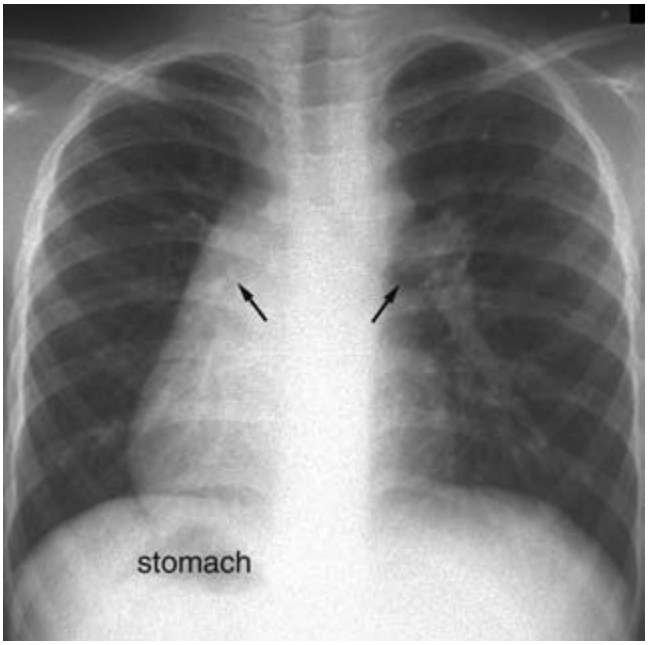

Fig. 34-2 Left isomeric bronchial branching. Frontal chest radiogram shows symmetrically long bronchi (arrows). The stomach bubble is seen below the right diaphragm and there is levocardia.

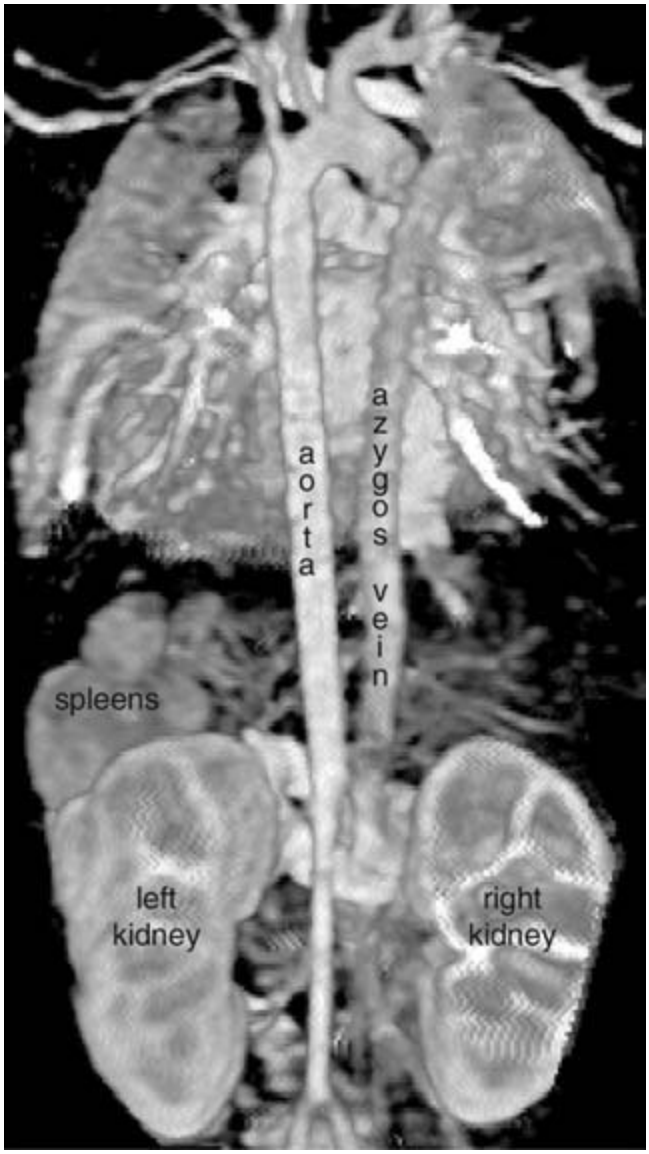

Fig. 34-3 Contrast-enhanced MR angiogram in coronal view seen from behind shows interrupted inferior vena cava with azygos venous continuation and polysplenia.

nary sinus or to the left-sided atrium. If this is not recognized before a Fontan procedure and dealt with, then postoperatively these patients may become progressively cyanotic because of hepatic venous–venous shunting (see Chapter 37). Hepatic vein connection to the coronary sinus or pulmonary venous atrium usually occurs in the setting of heterotaxy, particularly left isomerism/polysplenia, although this has been recorded in a patient with lateralized atria who developed pulmonary arteriovenous malformations. Interestingly, the pulmonary arteriovenous malformations resolved after the hepatic veins were diverted back to the right atrium.[60]

The angiographic and echocardiographic findings of this syndrome have been reviewed in detail elsewhere,[47,61–66] and there is now increasing experience with both computerized tomography and magnetic resonance imaging in patients with heterotaxia.[67–70]

Predisposition to atrial rhythm disturbances and congenital complete heart block

Intrinsic to hearts exhibiting left atrial isomerism is abnormal formation of the sinoatrial node, and thus it is not surprising that such patients may have a leftward and superior P-wave axis, so-called coronary sinus rhythm on their scalar electrocardiogram and may be prone to sick sinus rhythm.[71–74] An abnormal P-wave axis, leftward and superior, is found in about 50–75% of patients with left atrial isomerism, and complete heart block is far more common in patients with left isomerism than right isomerism.[72–74] Congenital complete heart block may exact its toll on the fetus with left atrial isomerism.[75] The morphology of congenital complete heart block in patients with left isomerism is discontinuity between the AV node and conduction axis.[71] Momma and his colleagues[73] reported the characteristics and natural history of abnormal atrial rhythms in left atrial isomerism. This group has had a long interest in the electrocardiograms of these patients and reviewed 450 tracings from 50 patients followed as long as 19 years. In 70%, the frontal P-wave axis was between –30° and –90°. Slow atrial rates below the second percentile were observed in 50%, and progressive slowing of the atrial rhythm was characteristic of these patients.

Extracardiac abnormalities

The extracardiac anomalies identified in the patient with left atrial isomerism have been fully characterized (see Chapter 33: Table 33-2).[1–23] These are often anomalies of midline-associated structures. The digestive tract abnormalities consist of malrotation of the intestine, preduodenal portal vein, gastric volvulus, esophageal hiatal, hernia and biliary atresia.[1–23] A short pancreas has also been observed as well as absence of the gall bladder. Important genitourinary, craniofacial, and musculoskeletal abnormalities have also been catalogued in these patients.[20–22,76]

Outcome analysis

We commented in the previous chapter on the prenatal recognition of patients with visceroatrial heterotaxia, and those specific markers that assist in this diagnosis. The fetal outlook is consistently poorer for those with left atrial isomerism and fetal complete heart block,[77] especially those developing first or second trimester heart block.[77,78] We have stated earlier that a form of atrioventricular septal defect is often present in patients with heterotaxy. This feature has been recognized in the prenatal detection of cardiac anomalies and the presence of associated cardiac anomalies worsens their outcome.[79–82] Interestingly while the fetal outcome is somewhat worse for patients with left isomerism compared with right isomerism, the reverse is true postnally.[29,30]

Franklin and his colleagues from Great Ormond Street Hospital for Sick Children in London have looked at the fate of patients with double-inlet ventricle presenting in infancy and who survived without definitive repair.[83] This retrospective review included 191 infants with double-inlet ventricle seen from 1973 to 1988. The actuarial survival rate before definitive repair for the entire cohort was 57% at 1 year, 43% at 5 years, and 42% at 10 years. Fourteen patients were recognized to have left isomerism and survival at 2 and 5 years was 65 ± 13% and 57 ± 13%, respectively, considerably better than for those with right atrial isomerism.

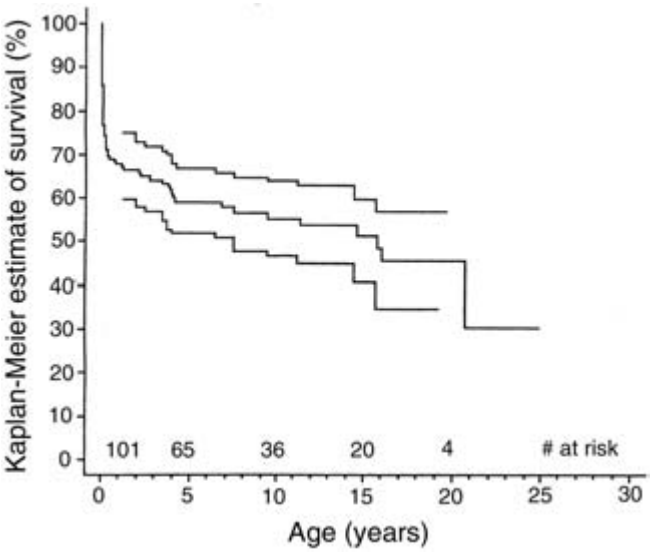

Fig. 34-4 Kaplan–Meier survival (central line) with 95% CL (outer lines) in 163 patients with left atrial isomerism. (Reprinted from Gilljam *et al.*,[30] Copyright (2000), with permission from The American College of Cardiology Foundation.)

There are a large number of reports of the outcomes of various surgical interventions for the patient with left atrial isomerism and heterotaxy. These reports detail the correction of anomalies of systemic and pulmonary venous connections; the Mustard or Senning repair for so-called isolated ventricular inversion (actually left isomerism with lateralized systemic and pulmonary veins); other forms of biventricular repair, and univentricular palliation.[84–92] In the first decade or so after univentricular palliation of the Fontan type was introduced, patients with atrial isomerism, right or left, were considered at higher risk for this form of palliation (see Chapter 36). The introduction of staging with a bidirectional cavopulmonary connection or hemiFontan has led to improved results as these maneuvers allow the surgeon to deal with important anomalies of systemic and pulmonary venous return. Important atrioventricular valve regurgitation has remained a difficult issue to manage, although there are some data indicating that volume unloading surgery may improve mild degrees of regurgitation. Imai and his colleagues have had a very large surgical experience repairing the regurgitant atrioventricular valve.[93] In their experience, Fontan mortality for patients without atrioventricular valve regurgitation was only 3%, but for those requiring atrioventricular valve surgery, Fontan mortality was higher at 12%. Actuarial survival for this latter group was 84% for years 5 through 10, and for those without atrioventricular valve regurgitation, survival at 10 years was 93%. It was the observation of this group that the cause of the regurgitation was mainly annular dilatation or prolapse of the leaflets. It is of interest that Imai's group addressed the atrioventricular valve regurgitation at the time of the Fontan, while others repair the valve at the time of staging and perhaps have a somewhat lower Fontan mortality. However, these reports all address the "tip of the iceberg"; that is, they address only those patients undergoing surgery (the numerator), not the outcome of the entire cohort of patients (the denominator).[30]

Gilljam and his colleagues from the Toronto Hospital for Sick Children reviewed the outcomes of all 163 patients with left atrial isomerism identified over a 28-year experience (1970–98).[30] These patients accounted for 0.4% of all new patients with congenital heart disease diagnosed at our institution during the study period. In 20 patients (12%), the diagnosis was made or suspected at fetal echocardiography. There were an additional 14 fetal cases who subsequently underwent termination of pregnancy or spontaneous fetal death. As in other reports, there is a preponderance of females (63%). Cardiac defects included interrupted inferior caval vein in 92%; anomalous pulmonary venous connections in 56%; atrioventricular septal defect in 49%; pulmonary stenosis or atresia in 28%; aortic coarctation in 16%; 10% severe systemic outflow tract obstruction and congenital complete heart block in 7%. Of 22 patients with a normal heart, 18% died of extracardiac anomalies. As one would expect, important extracardiac anomalies were identified in 58 patients or 36% of the entire cohort. Sixteen patients were found to have biliary atresia; 11 of these underwent a portojejunostomy and 4 of these went on to a liver transplant. The overall survival of the 163 patients was 80% at 1 month, 68% at 1 year, 59% at 5 years, 55 at 10 years, and 51% at 15 years (Fig. 34-4). During the study period, 20% of patients died shortly after birth or were not considered eligible for surgery due to the presence of complex cardiac malformations, associated anomalies, or severe prematurity. We divided the cohort into three groups: (1) patients with a structurally normal heart (or nearly so); (2) patients with balanced defects suitable for biventricular repair; (3) patients suitable only for univentricular palliation. There were 22 patients in the first group (13%); 71 in the second group (44%); and 70 patients in the third group (43%). Overall survival in group 1 was 82%; those with a biventricular heart (group 2) 66%; and for group 3, those suitable for univentricular palliation, 37% (Fig. 34-5). In multivariate analysis, three cardiac factors (complete atrioventricular block, single ventricle morphology, and coarctation of the aorta)

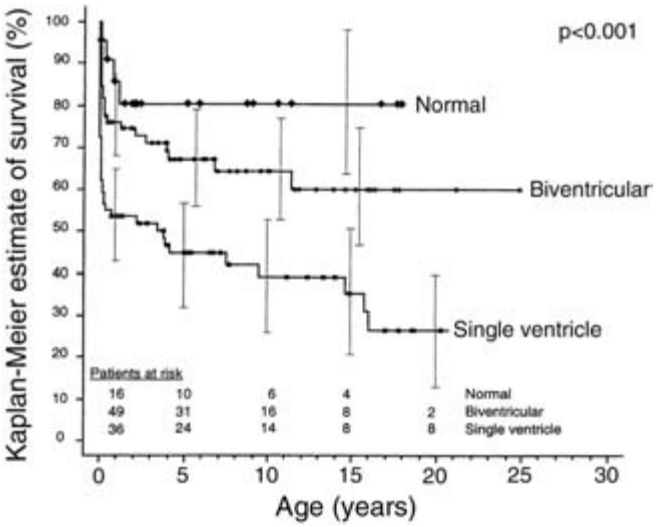

Fig. 34-5 Kaplan–Meier survival in 163 patients with left atrial isomerism and a normal heart ($n = 22$), a heart suitable for a biventricular repair ($n = 71$) and a heart suitable for single ventricle palliation ($n = 70$). Survivors are denoted by dots. Vertical bars represent 95% confidence limits. Differences between groups were analyzed using the log-rank and Wilcoxon tests. (Reprinted from Gilljam *et al.*,[30] Copyright (2000), with permission from The American College of Cardiology Foundation.)

were independently associated with increased mortality. In addition three extracardiac findings were associated with increased mortality, low birth weight, biliary atresia, and other important gastrointestinal malformations. Survival in the biliary atresia group was only 31%. With increasing experience and improving results with Norwood palliation, it is likely that results in the third group of patients should improve.[94] These patients will be subject to the panorama of complications that may jeopardize any survivor of Fontan palliation (see Chapter 37). Because many requiring single ventricle palliation have a common atrioventricular orifice and a functioning systemic ventricle of right ventricular morphology, the form and function of these two structures will be of considerable importance. The data published several years by Sinzobahamvya *et al.* and in 2001 by Azakie and his colleagues from Toronto demonstrate continued improving results in patients with left isomerism, and better results as well in patients with right isomerism surviving infancy.[91,95] Finally, some patients with left isomerism will have associated aortic atresia and these patients have been successfully palliated on a Norwood–Fontan tract.[96] The issue of the development of pulmonary arteriovenous malformations, their prevention and treatment will be fully discussed in Chapters 36 and 37. In this regard, the Kawashima operation and pulmonary arteriovenous malformations are also discussed in Chapter 37. A wonderful review of life and contributions of this surgical giant has recently been published.[97]

The Cavopulmonary Shunt

The surgical odyssey leading to right heart bypass is indeed an international one. Trusler and his colleagues,[1] Konstantinov and Alexi-Meskishvili,[2,3] Karl and Stellin,[4] and Robicsek[5,6] have all reviewed in detail the cavopulmonary shunt and have defined with clarity the origins of this bold and imaginative contribution. In a letter from Konstantinov and Alexi-Meskishvili to the editor of the *Annals of Thoracic Surgery*[3] in response to Karl's and Stellin's "Early Italian contributions to cavopulmonary surgery,"[4] they write: "It is always interesting to see how the same idea evolves in different groups working independently and often unaware of each other's efforts. It was undoubtedly Carlo A. Carlon, professor of surgery at the University Medical School in Padua, who first described the concept of the cavopulmonary shunt."[3] Konstantinov and Alexi-Meskishvili in their own paper wrote: "It often occurs in medicine that a syndrome or operation is named not after those by whom it was first described, but rather after those who convinced the world. William Glenn, was not the first to introduce the concept of cavopulmonary anastomosis. He reported neither the first experimental study, nor the first clinically successful operation. However, it was an extensive study undertaken by the Yale University group and prolific writing of Glenn published in the most-read surgical journals that finally convinced the world. By virtue of experimental and clinical work, Glenn's name is generally attached to the operation. None the less, a remarkable pioneering contribution of many other surgeons, namely, Carlon, Francis Robicsek, Nikolai Galankin, Tigran Darbinian, Harris Schumacker, and Evengenii Meshalkin should be remembered, respected, and never regarded as just a historical curiosity."[2] Robicsek, with his long interest in cavopulmonary connections[5,6] and indeed as one of the pioneers of this innovative operation, has also reviewed in two wonderful papers, the first of which was published two decades ago, the history of this operation, and those in the United States, Italy, and the Soviet Union who pioneered this innovative procedure.[5,6] In terms of William Wallace Lumpkin Glenn, Sewell and Glenn began their experimental work on right heart bypass in 1950 and Glenn and his colleagues continued this work throughout most of the 1950s.[2,5,6–10] Glenn's first experimental work on the cavopulmonary shunt was published with Patino in 1954.[7] The first report of an experimental method of performing an anastomosis between the superior vena cava and the right pulmonary artery was presented by Carlon, Mondini and deMarchi in 1950 and published in English the following year.[11] Their surgical connection utilized the azygos vein. These authors speculated that this procedure might be helpful in certain cardiac malformations. Glenn reported in 1958 the clinical application of the cavopulmonary connection (Fig. 35-1).[10] Before the introduction of the Fontan procedure,[12] the classic cavopulmonary shunt or Glenn shunt to the right lung and blood supply from the heart and/or a systemic-to-pulmonary artery shunt to the contralateral lung provided a "balanced" circulation and offered reasonably good long-term palliation As pointed out by Yeh and his colleagues, the Fontan operation[12] changed the objective of the cavopulmonary connection to one of staging to the Fontan, thus reducing the risk of a subsequent Fontan.[13] Like the Blalock–Taussig shunt, the Potts or Waterston shunt, the Norwood operation, the Damus–Kaye–Stansel operation, the Jatene operation, the designation "Glenn shunt" is firmly entrenched in our vernacular. In view of the international multifocal contributions to the cavopulmonary connection, this operation should be more appropriately designated the Carlon, Robicsek, Galankin, Darbinian, Schumacker, Meshalkin, Glenn operation!

The classical cavopulmonary shunt: the Glenn operation

The classical Glenn anastomosis between the right pulmonary artery and the superior caval vein has provided excellent long-term palliation for many forms of complex congenital heart disease since its introduction in the 1950s.[14–23] The classical Glenn anastomosis is constructed between the end of the divided right pulmonary artery and the side of the superior caval vein, with ligation of the azygos vein (Fig. 35-1). The superior caval vein is also ligated between the anastomosis and the right atrium to divert all superior caval return into the right pulmonary artery. Necessary for a satisfactory outcome of this operation is low pulmonary vascular resistance and an acceptable-size right pulmonary artery.[1] It is also important to determine whether or not there is a left superior vena cava and bridging brachiocephalic vein. If a left superior caval vein is present in the absence of a bridging innominate vein, but not recognized preoperatively, the patient would not benefit as much from this procedure. If the brachiocephalic vein is of appreciable caliber, the left superior vena cava can be ligated. In the absence of a left brachiocephalic vein, the left superior vena cava could be judiciously ligated, while measuring the venous pressure proximal to the ligation. thus ensuring that a cerebral venous infarction does not result.[24] Rarely ligation of a left superior caval vein will result in a myocardial infarction.[25–31] This occurs in those patients with coronary sinus ostial atresia where the left superior caval vein provides the conduit for egress of coronary venous blood (Fig. 35-2B).[25–31]

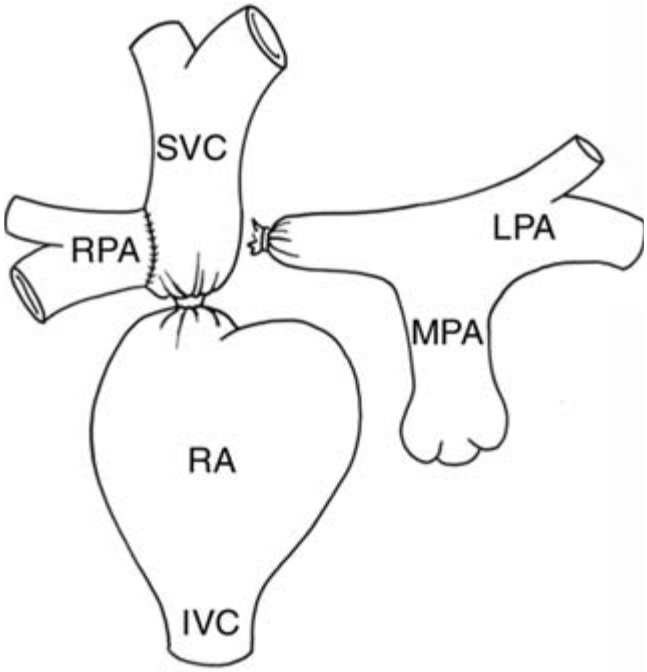

Fig. 35-1 Classical Glenn cavopulmonary anastomosis to the right lung. The superior vena cava (SVC) is connected to the divided right pulmonary artery (RPA) and the superior vena cava is ligated above its entrance into the right atrium (RA). IVC, inferior vena cava; LPA, left pulmonary artery; MPA, main pulmonary artery.

We reported in 1975, 1980, and 1982 our clinical experience with the classical Glenn anastomosis amongst other shunts.[23,32,33] In his Glenn lecture, Trusler and his colleagues reported on our entire Glenn experience to that time.[1] From 1961, the year of the first Glenn shunt performed in Toronto at the Hospital for Sick Children through 1988, 139 classical Glenn shunts were performed. Forty-five of these were performed for tricuspid atresia; 43 for single ventricle; 21 for complex transposition of the great arteries, 10 for pulmonary atresia and intact ventricular septum, and another 10 for miscellaneous conditions. The patients' ages ranged from 17 days to 17 years with a mean of 5.9 years. There were 8 early deaths in the series of 139 patients, seven in the first 39 patients and only one in the last 100. Patient survival rates were 84.9% at 5 years and 61.7% at 15 years. Shunt survival rates, from the time from creation of the shunt to the tie of the next palliative or reparative operation, were 61.1% and 31.8% at 5 and 10 years respectively. As one might anticipate after a classical Glenn anastomosis, decreased flow to the right upper lobe is apparent both from inspection of chest radiographs and from pulmonary perfusion scans.

A number of factors have been implicated in late deterioration of the functionality of the classical Glenn anastomosis as evidenced by increasing hypoxemia and polycythemia[34–42] (Table 35-1).

With growth of the patient, the upper-to-lower body ratio will change in a disadvantageous way, and this will lead to reduced benefit from this shunt.[43,44] That is why the cavopulmonary shunt is rarely used alone in the adult patient.[45,46] Isolation of the left pulmonary artery secondary to progressive closure of a ventricular septal defect or infundibular obstruction as in the patient with tricuspid atresia and normal ventriculoarterial connections previously palliated with a classical Glenn anastomosis is another anatomic reason responsible for late deterioration of the Glenn anastomosis.[1,19–23,34–42] Other reasons for late deterioration are diminished flow through the cavopulmonary connection caused by increased vascular resistance secondary to polycythemia and hyperviscosity. In some patients development of collateral venous circulation from the brachiocephalic vein or one of its tributaries bypassing the lungs and thus reducing

the effective pulmonary blood flow will also contribute to progressive hypoxemia (Fig. 35-2).[1,19–23,34–42] Others have suggested the decreased perfusion to the right upper and middle lobes reflecting the dependent nature of flow to the right lung characteristic of the classical Glenn anastomosis (Figs 35-2, 35-3).[41] Occasionally the site of ligation of the superior caval vein at the right atrial junction may recanalize, thus reducing flow to the right lung (Fig. 35-3).[47] Perhaps the most egregious cause of late failure of the classical Glenn anastomosis is the development of pulmonary arteriovenous fistulae (see next section in this chapter). Our data suggest this complication could be as high as 21%, with the potential for an increasing hazard of this complication with longer duration of the cavopulmonary shunt.[1,41] The role of hepatic vein exclusion is discussed in detail in Chapter 37. Suffice it to say, experience with the Kawashima operation and the development of pulmonary arteriovenous malformations suggested hepatic venous exclusion from the pulmonary circulation as one etiology.[48–51] It is likely far more complex than that. Some have advocated "fenestrating" the Kawashima operation in young infants to optimize postoperative hemodynamics.[51A]

In the era before the Fontan operation, once failure of the classical Glenn anastomosis has occurred, palliation could take the form of a systemic-to-pulmonary arterial shunt to augment flow to the contralateral lung. Others have advocated augmenting flow through the classical Glenn anastomosis by creation of an axillary artery-to-vein (or basilic artery-to-vein) fistula.[52–54] We previously reported our experience with this procedure which provides reasonable palliation.[54] We have augmented flow through either a classical Glenn anastomosis or bidirectional cavopulmonary connection in those patients not considered candidates for Fontan's operation. This maneuver affords some palliation, but at a cost of ventricular loading.[54] One of the late complications of this maneuver is aneurysmal transformation of the superior caval vein.[42] We have also found that the creation of an axillary artery-to-vein fistula may be difficult to take down at the time of a subsequent cardiac transplant (personal communication, Dr John Coles). We will consider the etiologies of acquired pulmonary arteriovenous malformations in the setting of the classical Glenn and bidirectional cavopulmonary connection later in this chapter.

The bidirectional cavopulmonary shunt

Construction of a bidirectional cavopulmonary shunt without ligation of the proximal right pulmonary artery was first performed by Achille Mario Dogliotti of Turin, Italy in 1961[55] and independently in dogs by Haller and his colleagues in 1964 (Fig. 35-4).[56] Azzolina, Eufrate and Pensa reported their experience with this technique in the patient with tricuspid atresia

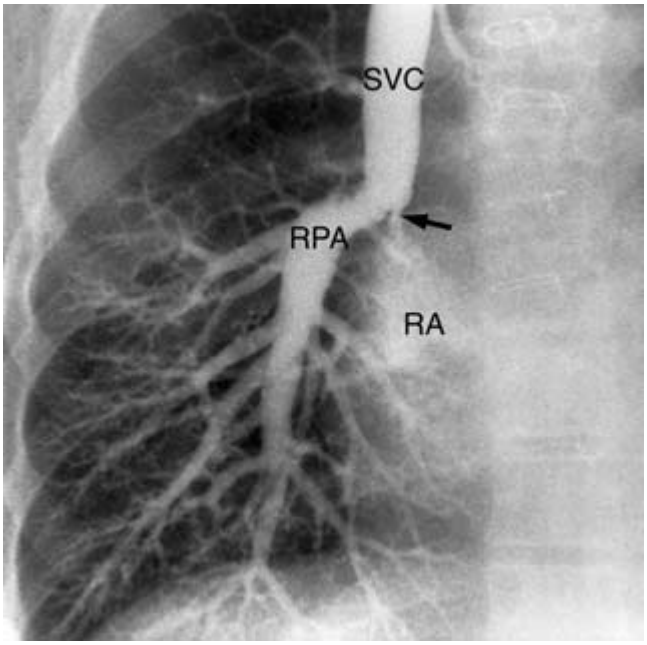

Fig. 35-3 Recanalization (arrow) of the ligated superior caval vein and underperfusion of the right upper lung after classical Glenn anastomosis. RA, right atrium; RPA, right pulmonary artery; SVC, superior vena cava.

in 1972.[57] There is now a large clinical experience with the bidirectional cavopulmonary connection.[58–99] This shunt utilizes an end-to-side anastomosis between the superior vena cava and the undivided right pulmonary artery. In those patients with a

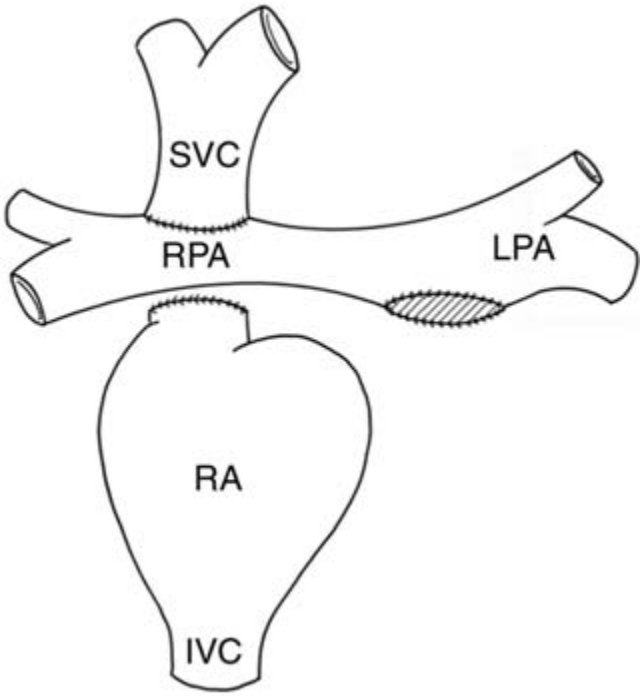

Fig. 35-4 Bidirectional cavopulmonary anastomosis. The superior vena cava (SVC) is divided and its cranial end is anastomosed to the incision in the right pulmonary artery (RPA). The cardiac end of the superior vena cava is oversewn. IVC, inferior vena cava; LPA, left pulmonary artery; RA, right atrium.

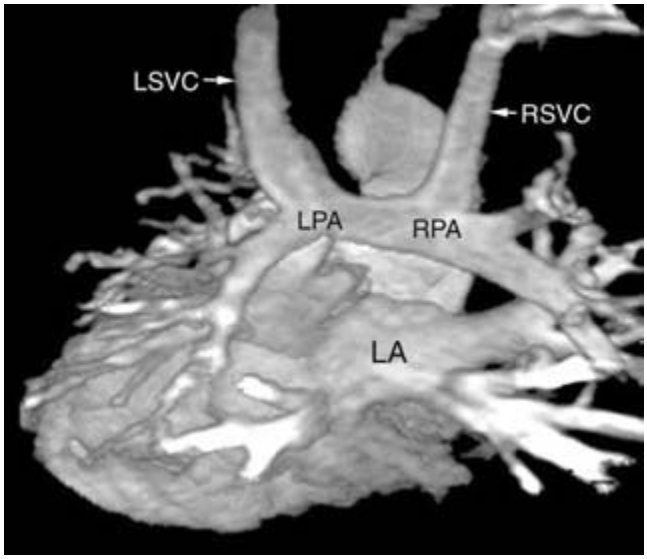

Fig. 35-5 Bilateral bidirectional cavopulmonary anastomoses. Contrast-enhanced MR angiogram seen from behind shows right and left superior venae cavae (RSVC and LSVC) connected to the right and left pulmonary arteries (RPA and LPA). LA, left atrium.

right and left superior vena cava but without a bridging brachiocephalic vein, it is necessary to perform bilateral bidirectional cavopulmonary connections (Fig. 35-5).[100] In the majority of patients undergoing a bidirectional cavopulmonary connection, flow from the heart into the pulmonary trunk is interrupted (so-called competitive blood flow), although this is not always the case as some patients are left with pulsatile forward flow (Fig. 35-6).[69,71,74–76,81–83] The bidirectional cavopulmonary connection has some advantages over the classical Glenn anastomosis, and is being applied to ever younger infants, some as young as a month of age.[59,61,62,66,73,77,78,91] The anastomosis is constructed in an end-to-side anastomosis thus allowing the caliber of the superior caval vein rather than the size of the ipsilateral pulmonary artery to define the size of the anastomosis. Secondly, the bidirectional cavopulmonary connection usually results in a higher oxygen saturation in young children reflecting the proportionately higher upper to lower body segment in younger children compared to older children.[64] In this regard, Salim and colleagues demonstrated that in healthy children superior vena caval flow rose from 49% of total cardiac output in the neonate to a maximum of 55% at 2.5 years, declining to the adult level of 35% by age 6.5 years.[44] As well, the bidirectional cavopulmonary connection provides flow to the contralateral lung without subjecting it to volume overloading and possibly pulmonary vascular obstructive disease from a systemic-to-pulmonary artery anastomosis to that lung, or inadequate growth and resultant hypoplasia from reduced flow. The bidirectional cavopulmonary anastomosis accomplishes these without volume-loading the ventricle, an important advantage for the patient with a univentricular atrioventricular connection.[1,58,59,63,64,67,69,77,78,84-89,92,98] Berman and Kimball found that a bidirectional cavopulmonary connection results in a significantly reduced ventricular preload and size while systolic ventricular performance is preserved.[101] This effect was more pronounced in those patients with single left ventricle morphology than in those with right ventricular morphology. Even with an additional source of pulmonary blood flow, a bidirectional cavopulmonary connection still volume unloads the single ventricle. Forbes and his colleagues looked at the influence of age at the time of the bidirectional cavopulmonary connection in ventricular unloading.[92] They found that the bidirectional cavopulmonary connection facilitates ventricular volume unloading and as well promotes regression of left ventricular mass in younger children, but was of questionable value in older children. As we discussed in considerable detail in Chapter 32, ventricular unloading has the potential for contributing to the development of systemic outflow tract obstruction in some patients with a double-inlet ventricle. The additional benefit of unloading the ventricle by construction of a bidirectional cavopulmonary connection is some improvement in the degree of atrioventricular valve regurgitation.[86–88] The final advantage to a bidirectional cavopulmonary connection is that the pulmonary arteries remain confluent, and this may prove important at the time of the Fontan procedure. Many have addressed the outcome of the bidirectional cavopulmonary shunt and the risk factors for early death, shunt failure, or necessity for bidirectional cavopulmonary shunt takedown. Among some of the risk factors identified with early mortality have been mean pulmonary artery pressure ≥ 18 mmHg, younger age at the time of surgery, abnormal pulmonary venous connections, heterotaxy, severe atrioventricular valve regurgitation. Alejos and colleagues have also suggested that right ventricular morphology is a risk factor for death or shunt failure.[72] Several years ago Reddy and his colleagues reviewed their institutional experience with the bidirectional cavopulmonary shunt.[77] Of the 120 bidirectional cavopulmonary connections performed in 120 patients from January 1990 to April 1996, 6 patients (4.9%) died in the early postoperative period and the overall early failure rate (death or takedown) was 8.1% (n = 10). By multivariate analysis, longer bypass time, age < 1 month, and higher pulmonary vascular resistance were significant risk factors for early shunt failure.[77] Including early and late mortality, actuarial survival rates at 1 and 2 years were 91% and 88%, respectively. Among the hospital survivors, the only

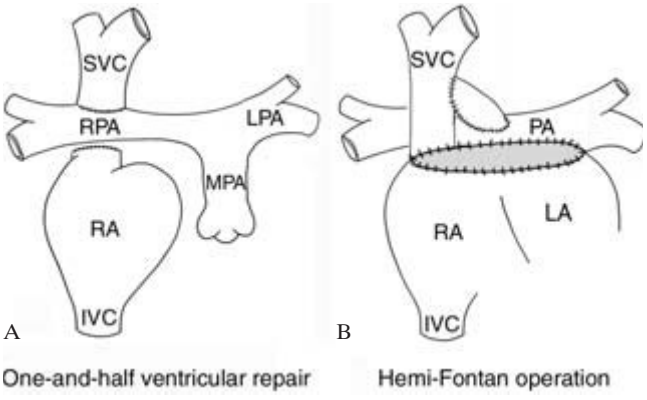

Fig. 35-6 Modifications of bidirectional cavopulmonary anastomosis. **A**. So-called one-and-half ventricle repair with pulsatile flow through the right ventricle into the main pulmonary artery (MPA). **B**. Hemi-Fontan operation. The roof of the right (RA) and left (LA) atria are anastomosed to a long incision on the inferior side of the confluent pulmonary arteries (PA). significant predictor of poorer survival by Cox regression was age < 2 months at the time of the initial cavopulmonary shunt.[77] Bradley and his colleagues found that elevated pulmonary vascular resistance was significantly associated with perioperative mortality.[91] An elevated pulmonary vascular resistance was associated with increased pulmonary artery pressure, decreased pulmonary blood flow, decreased effective pulmonary blood flow, and decreased aortic saturation.[91] Aeba and coworkers have studied those factors influencing arterial oxygenation early after the bidirectional cavopulmonary shunt in the absence of additional sources of pulmonary blood flow.[78] They found that there was a significant inverse relationship between the postoperative superior vena cava pressure and the arterial oxygen saturation. A low arterial oxygen saturation early after the bidirectional cavopulmonary shunt was a predictor of mortality or exclusion from univentricular repair within 24 months.[78] This group identified from multiple regression analysis that age < 8 months and ventricular volume overload predicted a lower arterial oxygen saturation after bidirectional cavopulmonary shunting.[78] We have also found that very rapidly after a bidirectional cavopulmonary connection, reopening of systemic venous collaterals can reduce effective pulmonary blood flow resulting in a concerning systemic arterial oxygen saturation (Figs 35-7 to 35-9).[42,102,103] Occasionally, the systemic venous collaterals develop to the left atrium or pulmonary vein as well as to the systemic veins (Figs 35-8, 35-10). Among these many studies no study has seemingly identified the same risk factors for early shunt failure. But most have identified higher pulmonary artery pressure and pulmonary vascular resistance as important predictors of shunt failure.

A number of studies have addressed growth of the right and left pulmonary arteries after a bidirectional cavopulmonary connection. Mendelsohn and his colleagues have studied the growth of the pulmonary arteries after a bidirectional cavopulmonary connection.[60] Serial angiographic and hemodynamic examinations before and 17.6 ± 1.6 months after bidirectional Glenn procedures were compared by these authors. At the follow-up study there was no significant change in diameter of the pulmonary artery ipsilateral to the bidirectional cavopulmonary shunt. Concerning, however, was the observation of a significant decrease in the diameter of the pulmonary artery contralateral to the bidirectional cavopulmonary shunt. There was also a 32% decrease in the Nakata index of total cross-sectional pulmonary artery area after the bidirectional Glenn procedure. In addition, total pulmonary blood flow and mean pulmonary artery pressure had decreased, but arterial oxygen saturation had increased at follow-up. The study of Slavik and associates indicates that the bidirectional cavopulmonary connection promotes growth of a small right pulmonary artery, but there is less evidence that it promotes growth of the small left pulmonary artery.[70] Reddy and his colleagues, using the indexed cross-sectional area of the lower lobe branch of the right and left pulmonary arteries, showed that pulmonary artery indices, including the lower lobe index, did not change significantly after bidirectional cavopulmonary shunt during medium-term follow-up and did not influence the Fontan outcome.[80] Penny and his colleagues measured pulmonary arterial size during cineangiography in 23 patients, 1.9 months before, and 14 months after bidirectional cavopulmonary connection. The measurements were standardized for body surface area using the method of Nakata and co-workers (pulmonary artery index). There was a significant reduction in pulmonary artery index after the bidirectional cavopulmonary connection, indicating that pulmonary arterial growth is impaired after the creation of a bidirectional cavopulmonary shunt.[104] They suggested this could be related to an absolute reduction in pulmonary arterial flow, and/or the loss of systolic expansion of the pulmonary artery.

Seliem and colleagues have studied lung perfusion patterns after the bidirectional cavopulmonary shunt.[97] They found sym-

metrical pulmonary blood flow distribution in only 27% of the patients, and moderately to severely abnormal pulmonary blood flow distribution in 35%.[97] As one might expect in those patients with moderately to severely abnormal pulmonary blood flow distribution, the right lung almost always had greater perfusion than the left lung. Reich and colleagues have quantitated the pulmonary blood supply in patients with bidirectional cavopulmonary anastomosis and pulsatile pulmonary blood flow using radionuclide angiocardiography.[105] Patients with cavocaval collaterals prevented quantitative analysis and thus were excluded from analysis. They found that the bidirectional cavopulmonary anastomosis provided 42.3% of total pulmonary blood flow. From the total bidirectional cavopulmonary anastomosis flow, 67.2% was directed to the ipsilateral lung. This lung received only 16.5 (3.3%) of all the blood from sources of pulsatile blood flow. The blood flow to the lung at the side of the anastomosis accounted for 35.3 (1.7%) of the total pulmonary blood flow. Non-pulsatile flow from bidirectional cavopulmonary anastomosis is mainly directed to the ipsilateral lung, whereas pulsatile flow is directed to the contralateral lung. Total perfusion of the

ipsilateral lung is less than the perfusion of the contralateral lung.[105]

The influence of competitive pulmonary blood flow on the bidirectional cavopulmonary shunt has been assessed in several centers.[69,71,74–76,78,81–83,106–110] The multi-institutional study of Webber and his colleagues showed that competitive flow is well tolerated in the short and medium term after bidirectional cavopulmonary shunt, with improvement in early, but not late, systemic arterial oxygen saturation.[74] These authors discuss the potential benefits of leaving some pulsatile flow including the prevention of development of pulmonary arteriovenous fistulae, the prevention of the development of systemic-to-pulmonary artery collaterals and as well the potential to enhance pulmonary arterial growth. The data of Mainwaring is more cautionary in the evaluation of the role of accessory blood flow, and they state that morbidity and mortality are increased in those patients with accessory blood flow.[75] The analysis of Frommelt and her colleagues indicates that an additional source of pulmonary blood flow in patients with a bidirectional cavopulmonary shunt usually results in higher oxygen saturations. However, the patients have higher central venous pressures, and they may be more at risk for late development of chylothorax.[76] Aneurysmal transformation of a left superior caval vein has also been reported as a complication of a pulsatile cavopulmonary connection.[71] As pointed out by Aeba and colleagues, it may be necessary to provide an additional source of pulmonary blood flow in those patients remaining hypoxemic after a bidirectional cavopulmonary shunt providing they have a low superior vena caval pressure.[78] Yamada and his colleagues have addressed the issue of bidirectional cavopulmonary shunt with additional source of pulmonary blood flow should be the definitive palliation for the functional single ventricular heart.[107] Their data do not support the clear superiority of long-term bidirectional cavopulmonary shunt over the construction of Fontan circulation for management of the functional single ventricular heart.[107] Miyaji found that the pulmonary artery area index showed a tendency to increase.[110] They also found that the mean number of risk factors for the Fontan procedure decreased significantly from 1.8 ± 1.1 to 0.7 ± 0.8 after the pulsatile bidirectional cavopulmonary shunt. A number of their patients initially considered too high risk for a Fontan went on to this definitive surgery after the pulsatile bidirectional cavopulmonary shunt.

We indicated earlier in this chapter that some patients without a brachiocephalic vein will require bilateral bidirectional cavopulmonary connections (Fig. 35-5). We have found that this is a risk factor for adverse outcome when compared to patients undergoing a unilateral bidirectional cavopulmonary shunt.[100] The overall outcome of 39 children requiring bilateral bidirectional cavopulmonary connections was compared to 274 children having a unilateral cavopulmonary anastomoses. Nine patients (23%) with bilateral superior venae cavae were found to have thrombus in the cavopulmonary circulation after the bilateral anastomoses (b-CPA) (Fig. 35-11). Postoperative mean arterial oxygen saturation was significantly lower in those who had thrombus ($69\% \pm 10\%$ vs. $82\% \pm 7\%$; $P < 0.01$). Thrombus formation was associated with mortality. The indexed superior venae cavae size was not a risk factor for thrombosis. In follow-up studies the connecting pulmonary artery segment between the two cavopulmonary anastomoses was smaller than the pulmonary arteries adjacent to the hilum. Survivors of a b-CPA were less frequently converted to a Fontan circulation at 5 years of follow-up (Kaplan–Meier 5-year estimates, 39% for b-CPA vs. 74% for u-CPA; $P = 0.02$). We concluded that bilateral superior vena cava-to-pulmonary artery anastomosis is associated with an increased risk of thrombus formation and unfavorable growth in the central pulmonary arteries. We speculated that

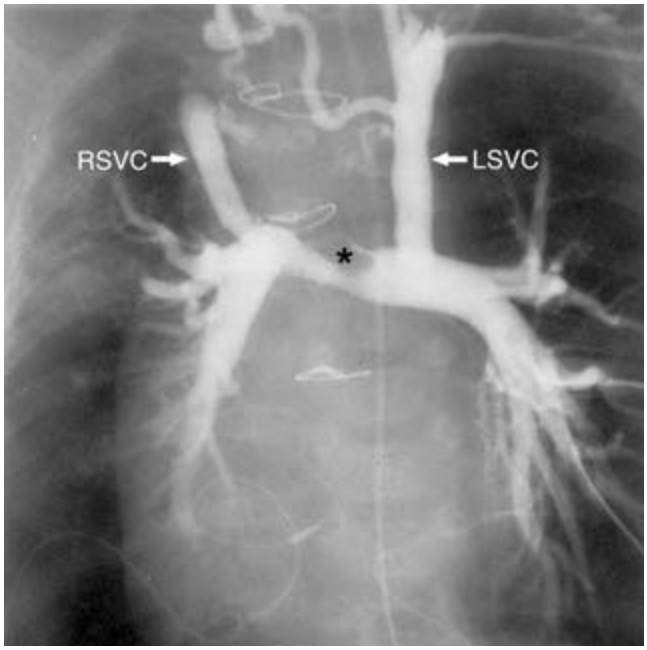

Fig. 35-11 Bilateral bidirectional cavopulmonary anastomoses. A thrombus (asterisk) is formed in the confluent part of the pulmonary artery. LSVC and RSVC, left and right superior vena cava, respectively.

anticoagulation therapy may be an important adjunct in children undergoing bilateral bidirectional cavopulmonary connections. The finding of increased tendency to shunt thrombosis after the bilateral bidirectional cavopulmonary shunts was also recognized by Forbes.[93] Thrombus can also develop as a complication of unilateral bidirectional cavopulmonary anastomosis (Fig. 35-12).

Systemic venous collateralization is very well documented after a bidirectional cavopulmonary shunt and this is likely to be progressive over time, reflecting the chronically elevated systemic venous pressures (Figs 35-7 to 35-9).[102,103,111–113] The development of these important collaterals leads to reduced flow to the lungs and a lower effective pulmonary blood flow, thus contributing to hypoxemia. We reported the incidence of systemic venous collaterals in 103 patients who had undergone a bidirectional cavopulmonary shunt.[111] Angiographically detectable systemic venous collaterals developed in 31% of the patients. The majority of these collateral vessels originated from the brachiocephalic vein or its junction with the superior vena cava, and many of these drained below the diaphragm. Collateral development was associated with an abnormal superior vena cava connection; increased mean pulmonary artery pressure and an increased mean pressure gradient between superior vena cava and right atrium. Similar findings have been reported by McElhinney and his colleagues who also found that in the patients who developed venous collateral channels, the mean transpulmonary pressure gradient early after the operation was higher, and the mean arterial oxygen saturation at follow-up was lower.[113] When necessary, such venous collaterals may be treated successfully with a variety of catheter-introduced devices or by video-assisted thoracoscopic surgery (Figs 35-7, 35-8).[42,114–116]

Systemic-to-pulmonary artery collateral vessels are well-known sequelae of cardiac surgery, particularly but not exclusively after a lateral thoracotomy (Fig. 35-13). McElhinney and his colleagues reviewed the angiographic and clinical data of 76 patients who had undergone a bidirectional cavopulmonary shunt between January 1990 and June 1996.[117] The median age at the bidirectional cavopulmonary shunt was 10 months and the median duration from the bidirectional cavopulmonary shunt to follow-up catheterization was 18 months. Arterial collateral vessels were detected in 59%. Those factors associated

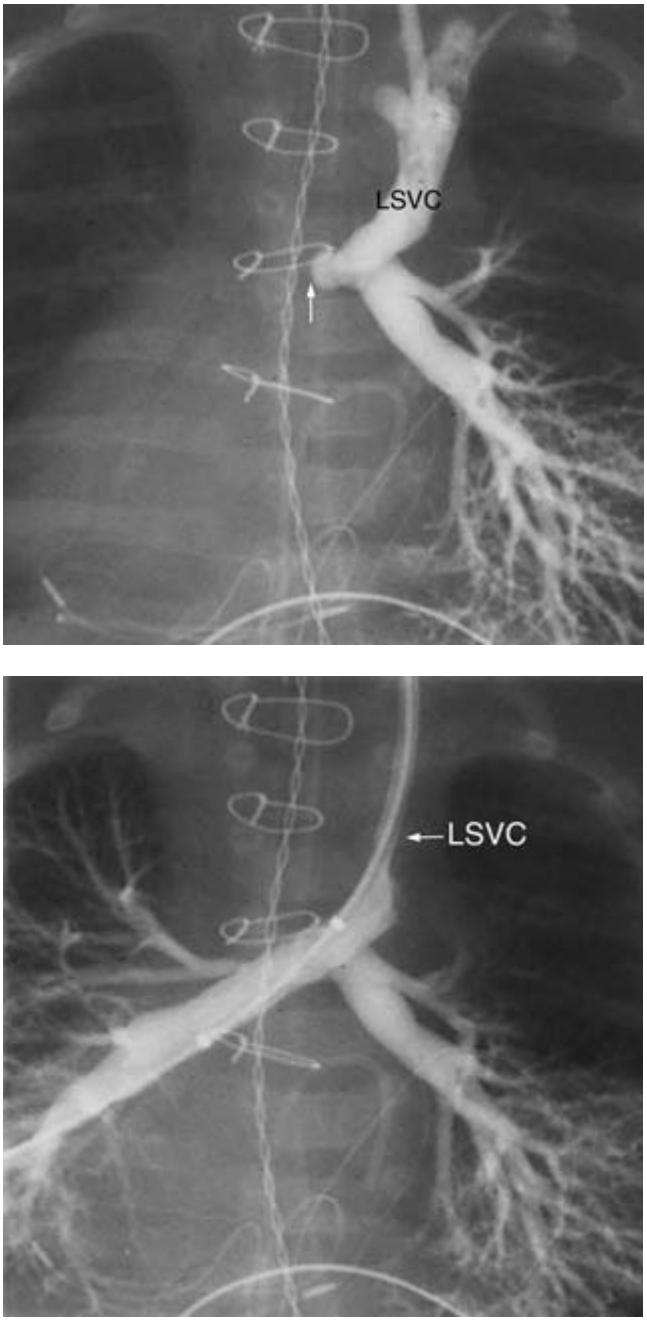

Fig. 35-12 Complete obstruction of the right pulmonary artery after left-side bidirectional cavopulmonary anastomosis in a patient with right isomerism. **A**. Injection into the left superior vena cava (LSVC) shows complete occlusion (arrow) of the functional right pulmonary artery due to thrombus formation within a narrowing segment. **B**. After removal of the thrombus thorough a catheter, the right pulmonary artery was dilated by placing a stent.

with collateral development included a prior right-sided systemic-to-pulmonary arterial shunt; a lower pre-bidirectional cavopulmonary shunt end diastolic ventricular pressure; a lower pulmonary vascular resistance; and the use and duration of cardiopulmonary bypass during the construction of the bidirectional cavopulmonary shunt. The majority of these arterial collateral arteries originate from the subclavian arteries, internal mammary arteries, and/or the thyrocervical trunk. They are best imaged by direct selective injection of contrast into the subclavian and internal mammary arteries. An injection into the descending aorta with distal balloon occlusion is also helpful. Although the clinical significance of these collaterals is unclear, some have suggested that pre-Fontan interruption of the larger collaterals may reduce Fontan mortality and morbidity, especially prolonged effusions.[118–122]

Sinus node dysfunction is a well-known complication of atrial surgery for transposition of the great arteries, and has been documented after the Blalock–Hanlon atrial septectomy, and the Mustard or Senning repair (see Chapter 25A). This dysfunction has been attributed to injury to the sinus node and to its artery. It is not surprising, therefore, to document sinus node dysfunction after a systematically staged Fontan procedure.[123–125] The morbidity and mortality of total cavopulmonary connection (modified Fontan procedure) may be decreased in many patients with single ventricle in whom the risk of surgery is high by performing the operations in a staged fashion.[125] Each operative intervention, however, exposes the sinoatrial node region to risk of injury, and it is likely that a staged approach could increase the risk of altered sinoatrial node function in these patients. Manning and his colleagues have addressed the impact of a stgaed approach to the Fontan on sinus node function.[125] Of 324 patients undergoing a Fontan operation, 227 had a Fontan operation without a prior cavopulmonary shunt (group 1) and 97 had a cavopulmonary shunt before a Fontan operation (group 2). They classified arrhythmias as altered sinoatrial node function, supraventricular tachycardia, or atrioventricular block. The prevalence of both transient (resolving before hospital discharge) and fixed (persisting until hospital discharge) altered sinoatrial node function was similar for the two groups after cavopulmonary shunt or primary Fontan despite a heterogeneous patient population (group 1: 10.6%/4.4%; group 2: 10.3%/3.1%; $P = 0.28$). Conversion from cavopulmonary shunt to Fontan in group 2 resulted in a higher prevalence of altered sinoatrial node function in the early postoperative period (transient: 23.7%; fixed: 23.7%; $P < 0.001$) and on follow-up (group 1: 7.7%; group 2: 16.7%; $P < 0.02$). In group 2, 40 of 82 patients without arrhythmia after first intervention (cavopulmonary shunt) had an arrhythmia after the second intervention (Fontan) (49%); of 14 with an arrhythmia after the first operation, 10 (71%) had one at the second intervention ($P < 0.01$). In conclusion, a multistaged operative pathway to Fontan reconstruction is associated with a higher early risk of altered sinoatrial node function. The occurrence of altered sinoatrial node function after cavopulmonary shunt is itself a risk factor for arrhythmia after the Fontan operation. In this regard, there is little information on the incidence of sinus node dysfunction after the classical Glenn anastomosis. Indeed, sinus node dysfunction was not mentioned by Trusler in his excellent Glenn lecture about the cavo-pulmonary shunt.

The Pediatric Cardiac Care Consortium consisting of nearly 40 participating centers have reported their data on outcome of the cavopulmonary connection. Since 1984 and through 1994, data were obtained on a total of 36 855 operations. Of these, 5447 were performed in neonates; 9566 on infants; 20 260 on children; and 1582 on adults. From 1985 to 1993, 567 Glenn shunts, bidirectional cavopulmonary shunts and hemi-Fontans were performed in patients aged between 29 days and 32 years (median 2.0 years) and with a median weight of 10.2 kg. These operations represented 2% of all the operations carried out by the consortium over this time interval. The principal diagnoses were single ventricle in 29%, tricuspid atresia in 23%; hypoplastic left heart syndrome in 9%; pulmonary atresia and intact ventricular septum 8%; mitral atresia in 6%; and complex pulmonary stenosis or atresia in 6%. The overall mortality for this experience was 8.8%, with the mortality slightly higher in infants at 11.3% compared to children 7.8% and adults 8.3%. Mortality was higher in the neonates and in those with a somewhat lower body weight. Mortality was lower for those with tricuspid atresia or mitral atresia when compared to those with the hypoplastic left heart syndrome. Interestingly, in the consortium data, heterotaxia had no statistically significant influence on mortality. The study consisted of 91 patients with heterotaxia with a mortality of 12.1% and 475 patients without heterotaxia with a mortality of 8.2%. The length of stay was analyzed in the 517 survivors. The median length of stay was 10 days, ranging from 3 to 220 days. The age at operation influenced the length of stay, being longer in the very young infant and this was true for those with the lowest body weight. The diagnosis also correlated with the length of stay, with hospitalization of patients with Ebstein's anomaly of the tricuspid valve (mean 23.5 days). Mitral atresia (mean 21 days), and hypoplastic left heart syndrome (mean 19.2 days) were longer compared to the shorter stay for patients with tricuspid atresia (mean 13.2 days), complex pulmonary stenosis (mean 10.4 days), complex pulmonary atresia (mean 10.2 days), and pulmonary atresia and intact ventricular septum (mean 12.2 days).

The bidirectional cavopulmonary connection as definitive palliation

Some cardiologists have suggested that the bidirectional cavopulmonary shunt could be definitive palliation, the inference being that this operation will provide excellent long-term palliation without subjecting the patient to the risk of the Fontan.[107,126] This acknowledges as well the reality that there is no such outcome as the "perfect" Fontan.[127] We have provided data to suggest that survival following the cavopulmonary shunt is equivalent, with or without the Fontan.[13] In our institution from 1962 to 1997, 490 patients had a cavopulmonary shunt, excluding those who had a cavopulmonary shunt concomitant with a Fontan. We excluded an additional 55 patients in whom the cavopulmonary shunt was performed at or after a biventricular repair or after a Fontan. This left 435 patients in the analysis. The long-term survival 20 years after a cavopulmonary shunt is 56 ± 5% for the entire cohort of 435 patients. Survival from birth for 407 patients with a cavopulmonary shunt was 82% at 10 years, 65% at 20 years, 54% at 30 years, and 32% at 40 years. Survival at 20 years among the 220 patients who were subsequently converted to a Fontan circulation is 65 ± 8% compared to 50 ± 11% for the 187 patients who did not have a Fontan. Most of the apparent survival difference is because all early deaths after a cavopulmonary shunt occurred in the non-Fontan group. Multivariable analysis demonstrated that proceeding to a Fontan did have a small survival advantage which was not evident by univariate analysis. We also found that independent risk factors for death at any time were previous pulmonary artery banding or a common atrioventricular valve. The era of operation had no effect on survival. The mortality of 216 patients managed before 1992 is 6.0% and for the 219 patients after 1992, 8.3%. The late mortality after a cavopulmonary shunt was 23 of 179 patients (12.8%) in the era before 1992 and 9 of 196 patients (4.6%) in the recent era. Thus our data showed only a slight advantage in converting patients to a Fontan after a cavopulmonary shunt. And, in our hands, a marked reduction in the age of the cavopulmonary shunt and at Fontan has as yet not improved survival. How does one use these observations? Firstly, survival is but one aspect of any outcome analysis, and our data do not address functional outcome. Williams in discussion of this paper stated that in the patient with a stable cavopulmonary shunt, whom you consider at high risk for a Fontan, these data provide reason for not proceeding to a Fontan. Finally, the bidirectional cavopulmonary shunt has been used as an adjunct to biventricular repair.[128–134] The criteria for the performance of this combination of operations, namely biventricular repair and bidirectional cavopulmonary shunt, are unclear. Hanley in a recent editorial raises the question as to whether this approach confers any more benefit to the patient than the Fontan.[134] Other maneuvers have been introduced into the staging sequence such as the bidirectional inferior vena cava–pulmonary artery shunt.[135] We have had no experience with this operation, but certainly it would raise the hepatic venous pressure. We have used the bidirectional cavopulmonary shunt to palliate the infant with a large fibroma obstructing both the right ventricular inlet and outlet.[136]

Ventricular unloading: the downside

There is ample evidence that the bidirectional cavopulmonary shunt is advantageous in terms of palliation for the functionally univentricular heart.[67,96,99,101] It eliminates the inefficiency of pulmonary recirculation, and by reducing the volume load of the ventricle, this maneuver facilitates advantageous ventricular remodeling.[50] Important atrioventricular valve regurgitation may be improved after the construction of a bidirectional cavopulmonary shunt as shown by Mahle and others.[77,86] It may reduce early mortality and Fontan failure and this operation has been loudly praised in this regard.[67,96,99,101] However, we have already discussed the concern that the bidirectional cavopulmonary shunt may prevent the normal growth of the pulmonary arteries, especially that of the contralateral lung. There is also information that we have summarized indicating that staging to the Fontan may promote sinus node dysfunction (see also Chapter 37). An unusual complication subsequent to the bidirectional cavopulmonary shunt has been reported by Imanaka and colleagues.[137] Two patients both with pulmonary atresia, intact ventricular septum and major right ventricular coronary artery communication developed thrombosis in the right ventricle early after bidirectional superior cavopulmonary shunt.[137] They speculate that in this particular situation anticoagulation may prevent this complication.[137] In another situation as well, ventricular unloading and ventricular remodeling may be disadvantageous. Ventricular unloading is one factor contributing to systemic ventricular outflow tract obstruction in those hearts predisposed to this complication.[138–144] This complication and its management will be discussed in detail in Chapters 32 and 36. In the absence of competitive pulmonary blood flow, is the bidirectional cavopulmonary shunt causal to the development of pulmonary arteriovenous malformations?

The development of pulmonary arteriovenous fistulae

One of the fascinating chapters in the Quixotic quest to palliate the patient with a functionally single ventricle is the development of pulmonary arteriovenous malformations. This development provides a wonderful paradigm for bed-to-bench research.[145] Young infants and children are known to have primordial arteriovenous connections in their lungs which may reopen acutely leading to the development of clinically significant intrapulmonary right-to-left shunting.[145A] Yet, there is no simple etiology for the development of pulmonary arteriovenous malformations after cavopulmonary shunt surgery, or after the Fontan. Pulmonary arteriovenous malformations are intrinsic to the Weber–Osler–Rendu syndrome and have been seen in other patients with a structurally normal heart and without any internal stigmata of the Weber–Osler–Rendu syndrome.[42,146–152] First likely observed by Mathur and Glenn in 1973 in their long-term evaluation the classic cavopulmonary artery anastomosis,[21] the development of pulmonary arteriovenous malformations after the classic Glenn anastomosis was next fully documented by McFaul and his colleagues in 1977 (Fig. 35-14).[38] Citing the observations of Samanek and his colleagues who documented maldistribution of flow after the Glenn anastomosis to the right lower lobe using radioisotope imaging,[146] McFaul and his colleagues wondered whether absence of pulsatile flow contributed to their development,[38] a suggestion also proposed some years later by Cloutier and his colleagues.[41] Boruchow and his colleagues also noted these changes at angiography, but attributed the reduced flow to the right upper lobe to hypoxemia and secondary pulmonary vasoconstriction.[35] Yet the majority of patients after the Fontan procedure do not demonstrate symptomatic pulmonary arterio-

venous malformations, and thus absence of pulsatile flow to the lungs cannot be the only factor responsible for their genesis. There is an extensive literature addressing the frequency and possible etiologies of pulmonary arteriovenous fistulae which have been observed after the construction of a classical Glenn anastomosis, following total cavo-pulmonary bypass as part of the Kawashima operation; following the Fontan operation; and they have been recognized in patients with the polysplenia syndrome.[1,5,16,17,19–22,38–42,48–51,153–167] In 1 patient, with polysplenia, the cardiac malformations included dextrocardia, bilateral left atrial appendages, intact atrial and ventricular septa, interruption of the inferior vena cava, and connection of all the hepatic veins to the left-sided atrium.[165] One would wonder whether the hepatic veins were isolated from the pulmonary arterial bed, a suggestion from Srivastava and his colleagues as to the etiology of the development of pulmonary arteriovenous fistulae.[51] This patient also had hypoplasia of the portal vein, perhaps reminiscent of the hepatic–cirrhotic role in the genesis of pulmonary arteriovenous fistulae.[168–176] Many other patients with polysplenia/left isomerism have now been found to have pulmonary arteriovenous malformations, but in at least one patient the hepatic venous connections were shown to be normal.[166] It is of interest, however, that reversal of cirrhosis-related pulmonary shunting has been achieved in children by orthotopic liver transplantation,[168–176] lending credibility to the hepatic factor theory. Fewtrell and colleagues have fully analyzed intrapulmonary shunting in the biliary atresia/polysplenia syndrome and have demonstrated reversal after liver transplantation.[172] Summarizing their data, 173 children, including 93 with biliary atresia, received liver grafts at Addenbrooke's Hospital between 1983 and 1993. Of these, only 7 developed cyanosis owing to intrapulmonary shunting as a complication of their liver disease, and all 7 of these had the biliary atresia/polysplenia syndrome. Intrapulmonary shunting was confirmed by a radioisotope scan in 4 children. Only one child with the syndrome did not have cyanosis when undergoing transplantation. Seven of the 8 children are alive 6–54 months after transplantation, with normal pulmonary and hepatic function. Cyanosis recurred in 1 child who developed chronic rejection with liver failure. They concluded that: (1) there is a strong association between the biliary atresia/polysplenia syndrome and cyanosis due to intrapulmonary shunting; (2) intrapulmonary shunting is fully reversible after successful liver transplantation; (3) cyanosis, once present, is progressive, and these children should be considered for liver transplantation as soon as it occurs. Knight and Mee and then others have demonstrated reversal of acquired pulmonary arteriovenous fistulae which developed soon after a classic Kawashima procedure (see Chapter 36).[155–158,177–179] They diverted hepatic venous blood to the pulmonary arteries with a left lateral atrial tunnel. Laks and his colleagues have provided a modification of Fontan's procedure where the superior vena cava is connected to the left pulmonary artery and the lateral tunnel and thus the inferior caval vein and hepatic veins are diverted to the right pulmonary artery.[180] They caution that lack of hepatic venous flow to the left lung might contribute to unilateral pulmonary arteriovenous malformations, and this is exactly what we have observed in 1 patient who has undergone this operation. Lee and his colleagues have reported a child who, at the age of 6 years, became cyanotic, indeed progressively so over the next 3 years.[181] He was found to have an interrupted inferior caval vein with an azygos continuation. Both atrial and ventricular septa were intact, but all his hepatic veins drained into the pulmonary venous atrium.[181] Because pulmonary arteriovenous malformations were not clearly demonstrated by angiography, he underwent a bubble echocardiographic study which was confirmatory of pulmonary arteriovenous malformations.[182] The abnormal hepatic

venous connections were confirmed at surgery where they also documented that the coronary sinus drained as well into the pulmonary venous atrium. Surgical repair involved the diversion of the hepatic flow to the systemic venous atrium.[181] His preoperative oxygen saturation was 76%, and 3 weeks postoperatively, his oxygen saturation measured 95% and at 5 months 100%. At this time a bubble echocardiographic study was normal, confirming resolution of the pulmonary arteriovenous malformations. Thus this child did have forward pulsatile flow, but complete hepatic venous exclusion.[181] Similar resolution of pulmonary arteriovenous malformations has been reported in a patient who underwent repair of total anomalous systemic venous return[181A] and after other procedures to redirect hepatic venous flow to the lungs.[182D]

But the issue of exclusion of hepatic venous blood as causal to the development of pulmonary arteriovenous malformations is not "an all or none phenomenon." Unequal distribution of hepatic venous flow has been attributed to the causality of pulmonary arteriovenous malformations[162,163] and Uemura and colleagues and our group have redirected hepatic venous flow to remedy this complication.[162,163] Usually the development of pulmonary arteriovenous malformations following cavopulmonary surgery is one of progressive and inexorable deterioration. Less commonly their development can be rapid and severe.[179,183,184] The occurrence of symptomatic pulmonary arteriovenous malformations after a Fontan procedure is very uncommon if hepatic venous blood is conveyed to the lungs. Moore and his colleagues did report the development of pulmonary arteriovenous malformations after modified Fontan procedures in 2 patients.[161] However when one carefully reviews their case reports, it is apparent that the first patient had left isomerism with azygos continuation of the interrupted inferior vena cava, a univentricular heart of right ventricular type with a common atrioventricular orifice, single atrium, bilateral pulmonary arterial stenoses, and anomalous pulmonary venous connections. Following palliation with a left Blalock–Taussig shunt, she underwent a modified Fontan procedure at 5 years of age where the hepatic veins were diverted into the left pulmonary artery via a Gore-Tex vascular graft.[161] By 8 years of age, she had once again become cyanotic and she underwent a cardiac catheterization at 10 years of age which showed unilateral right-sided pulmonary arteriovenous malformations on selective right pulmonary artery angiography, a finding confirmed by saline contrast echocardiography. The left pulmonary artery was normal. The second patient of this report also had left isomerism with azygos continuation of the interrupted inferior vena cava to a left-sided superior caval vein and complex congenital heart disease.[161] He required pulmonary artery banding at 1 month of age and underwent a modified Fontan procedure at 7 months of age, but postoperatively the hepatic veins continued to drain into the atrium as in the classical Kawashima operation.[48–50] Postoperatively the cyanosis initially improved, but by 14 months of age, the cyanosis had worsened. A cardiac catheterization performed at 22 months of age demonstrated that the hepatic veins were the only source of an intracardiac right-to-left shunt. Pulmonary angiography demonstrated dilatation of those branch arteries supplying the middle and lower lobes of both lungs with early return of contrast material to the pulmonary veins. Again, saline contrast echocardiography with injection into the main pulmonary artery resulted in dense opacification of the pulmonary venous atrium.[161] Thus in both patients either partial (patient 1) or complete hepatic venous exclusion (patient 2) were likely responsible at least in part for the development of the pulmonary arteriovenous malformations.[48–51]

The exact prevalence of pulmonary arteriovenous malformations has been difficult to determine as their recognition depends on the methodology used to determine their presence. Bernstein and coworkers using contrast echocardiography found an incidence of pulmonary arteriovenous malformations to be 60%, and this complication was found to be higher in patients < 6 months of age and in those with heterotaxia.[185] Mahle and his colleagues using angiographic findings found that only 10 patients of 372 had pulmonary arteriovenous malformations (3%). The angiographic criteria included dilated distal pulmonary arteries, a classic reticular pattern in the late arterial phase, and rapid arterial-to-venous transit time as evidenced by simultaneous opacification of larger pulmonary arteries and veins.[51] We suspect that 3% is too low, and that positive angiographic findings would be a rather late finding.[42] This is exactly what was found by Chang and coworkers.[182] They compared bubble contrast echocardiography and pulmonary angiography in detecting pulmonary arteriovenous malformations. They found that 71% of patients studied with bubble contrast echocardiography had positive studies indicating the presence of pulmonary arteriovenous malformations compared with 21% detected by angiography.[182] All of their patients with complete hepatic venous exclusion had positive bubble contrast studies, while only 15.9% of those whose pulmonary circulations received hepatic venous were positive.[182] Others have also suggested the utility of contrast echocardiography in the detection of pulmonary arteriovenous malformations.[182A-C] Most of these studies support the increased sensitivity of contrast echocardiography as compared to angiography.

The numerous investigations cited in the last few paragraphs indicate that the etiologies of pulmonary arteriovenous malformations are complex and are not necessarily nor invariably related to lack of pulsatile flow nor to some hepatic factor. Kurotobi and colleagues have shown that patients after bidirectional cavopulmonary shunt show pulmonary endothelial functional attenuation and, of more importance, that decreased pulsatility of cavopulmonary flow is mainly responsible for this endothelial abnormality.[82] Technicium-labelled albumen microspheres have been used to detect intrapulmonary right-to-left shunting, and by inference pulmonary arteriovenous malformations.[186] All the patients studied with technicium-labelled albumen microspheres by Vettukattil and colleagues who had undergone a bidirectional superior cavopulmonary anastomosis were shown to have intrapulmonary right-to-left shunting.[186] This finding was also confirmed in those patients with a bidirectional superior cavopulmonary anastomosis who had as well competitive pulmonary blood flow. However, when quantified, those with competitive pulmonary blood flow had less intrapulmonary right-to-left shunting than those without competitive flow.[186] Kim and coworkers have confirmed these findings, showing that most patients with a bidirectional cavopulmonary connection as well as those with a total cavopulmonary shunt have subclinical evidence of right-to-left intrapulmonary shunting.[164]

It has been suggested for some years that angiogenesis may be responsible in part for the development of pulmonary arteriovenous malformations,[51,187] and perhaps the liver is responsible for the formation of an inhibitor of angiogenesis. What are the histologic correlates to the clinical findings of pulmonary

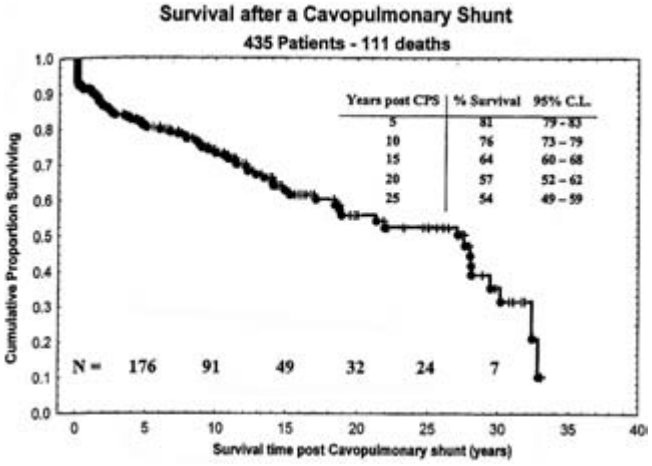

Fig. 35-15 Data from the Toronto Hospital for Sick Children. Kaplan–Meier curve showing survival after a cavopulmonary shunt in 435 patients with 111 deaths, 31 early and 80 late. arteriovenous malformations? It has been shown that in the areas of pulmonary arteriovenous malformations, the lung pathology is characterized by large dilated blood vessels or lakes and clustered smaller vessels or chains.[188] In addition, electron microscopy demonstrated in these vessels discontinuity of the basement membrane and endothelium.[188] Microvessel density has been shown to be a marker of angiogenesis.[189] Starnes and her colleagues have shown an increase in pulmonary microvessel density after cavopulmonary anastomosis, even in the absence of clinically apparent or symptomatic pulmonary arteriovenous malformations.[189] This observation supports the presence of a constant angiogenesis stimulus.[189] Furthermore, children with clinically apparent pulmonary arteriovenous malformations demonstrate large numbers of greatly dilated pulmonary microvessels, a finding absent in asymptomatic children after cavopulmonary bypass. The corollary to this observation is that it is likely and reasonable that the transition to clinically apparent pulmonary arteriovenous malformations may be due to influences that lead to vessel dilatation and remodeling.[187–189] Despite the presence of increased pulmonary microvessel density which suggests active tissue angiogenesis, immunohistochemical studies did not demonstrate greatly increased endothelial proliferation.[188,189] In a lamb model operated on to create an end-to-end superior vena cava-to-right pulmonary artery anastomosis, contrast echocardiography detected pulmonary arteriovenous shunting in all lambs evaluated 56 days or later.[190] Malhotra and coworkers showed using this model that superior cavopulmonary anastomosis results in an early but reversible reduction in activity and expression of angiotensin-converting enzyme, thus causing a decreased circulating level of the vasoconstrictor angiotensin II.[190] They went on to suggest that these results indicate that the ability of the pulmonary endothelium to regulate vascular tone is inhibited by the superior cavopulmonary anastomosis.[190] Starnes and her colleagues have also studied whether angiogenic proteins are increased in the lungs of children after cavopulmonary anastomosis.[191] They found that after cavopulmonary anastomosis patients demonstrated increased staining for vascular endothelial growth and its receptor and decreased staining for CD31. These findings are consistent with an increased angiogenic state, but interestingly, despite increased microvessel density, these vessels did not appear to be highly proliferative using PCNA staining.[191] The clinical observations involving the role of the liver support the hypothesis that normal vascular tone is maintained by a fine balance between stimulatory and inhibitory influences.[186,188,192,193] Vettukattil and colleagues believe that the factor(s) associated with the inhibitory effect on vasodilation are supplied in part by the liver, and that this hepatic factor is largely or completely removed by the systemic circulation in its first pass, resulting in its insignificant concentration in the superior venal caval blood.[186] They go on to suggest that unopposed precapillary and capillary vasodilation would follow in those parts of the lung perfused by blood without the hepatic factor (or without adequate amounts of hepatic factor). In view of these findings it would be interesting to create an animal model of an inferior vena caval-to-pulmonary artery bidirectional or unidirectional anastomosis and to study both the histopathology of the lung as well as using the specific immunohistochemical staining techniques to define the presence of angiogenic proteins, etc. In this regard, it would be interesting to know if patients palliated with a bidirectional inferior vena cava–pulmonary artery shunt developed pulmonary arteriovenous malformations.[135] Competitive pulmonary blood flow has been shown in some studies to reduce the severity of pulmonary arteriovenous malformations,[74,164,186] perhaps by conveying some of this hepatic factor to the pulmonary arteries, or from the pulsatility of the blood flow, or some combination thereof. Starnes and his colleagues showed that vascular endothelial growth factor and basic fibroblast growth factor were both increased in children with cyanotic congenital heart disease, possibly suggesting that the widespread formation of collateral vessels is mediated by these growth factors.[194] Malhotra and colleagues developed an ovine model that demonstrated the cavopulmonary anastomosis induced pulmonary expression of the angiotensin II receptor family, reliably inducing the development of pulmonary arteriovenous malformations eight weeks after a cavopulmonary connection.[194A] Finally,

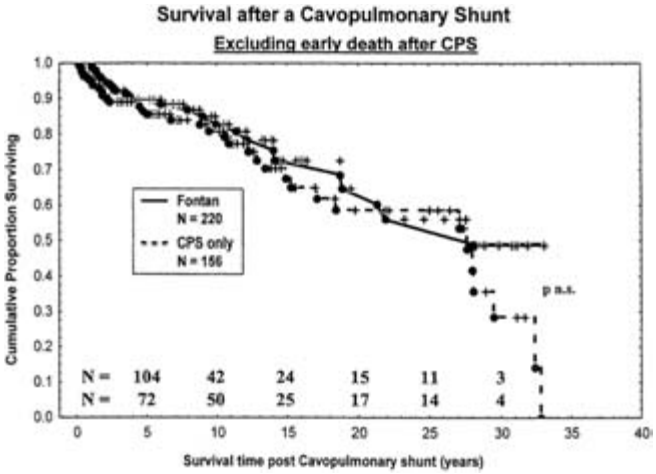

Fig. 35-17 Kaplan–Meier curves showing survival after a cavopulmonary shunt comparing 220 patients who went on to a subsequent Fontan with 187 who had no further definitive surgery. There is no significant difference in survival. (Reprinted from Yeh *et al.*,[13] Copyright (1999), with permission from Elsevier.)

Ashrafian and Swan in a scientific letter suggest that members of the transforming growth factor ß polypeptide superfamily or more precisely their antagonists may have an important role in the pathogenesis of pulmonary arteriovenous malformations after a superior cavopulmonary anastomosis similar to their role in the pathogenesis of pulmonary arteriovenous malformations in patients with hereditary hemorrhagic telangiectasia.[194B] In the conclusion of this letter, they ask the fundamental and provocative question: "why is the pulmonary circulation somatically modulated by the hepatopulmonary axis?"[194A]

The terms bidirectional cavopulmonary shunt and hemi-Fontan have been used interchangeably.[59,98,195] But there are differences as pointed out by Douville and colleagues.[84] After this procedure the physiology is that of a bidirectional cavopulmonary shunt, but all aortopulmonary shunts and ventriculopulmonary connections have been interrupted. This unloads the ventricle of all pulmonary work and any other potential Fontan risk factors have been corrected.[84] Most of the discussion thus far has focused on systemic venous and arterial collateralization, growth (or lack of) of the pulmonary arteries, the effect of competitive pulmonary blood flow and the development of pulmonary arteriovenous malformations. We should remember that protein-losing enteropathy and intestinal lymphangiectasia have developed after the classical Glenn anastomosis as has late-onset superior vena caval syndrome.[36,37] One of the dreaded complications of the Fontan procedure is the formation of acellular bronchial casts, the syndrome of plastic bronchitis.[196–203] This has been seen after the bidirectional cavopulmonary shunt as well. We have been reminded that persistence of the hepatic venous plexus with underdevelopment of the infrahepatic inferior vena cava[204,205] may exaggerate hypoxemia after the Kawashima operation.[48–50] We have learned much thus far about the bidirectional Glenn or hemi-Fontan (Figs 35-15 to 35-17), but the scientific derivatives of this clinical experience continue to challenge us as we evolve from the Glenn to the Fontan.[206]

In summary, there is now a 50-year history of the cavopulmonary shunt.

- The development of the cavopulmonary shunt is truly international in scope.
- The classical Glenn shunt provided excellent long-term palliation.
- This operation has the potential to lead to isolation of the contralateral pulmonary artery.
- Late failure of the classic cavopulmonary shunt can be attributed to several reasons, but the most egregious is the development of pulmonary arteriovenous fistulae.
- The bidirectional cavopulmonary shunt has been used for > 20 years usually as a staging maneuver to the Fontan.
- There is still discussion as to the merits of forward pulmonary blood flow in this situation.
- Systemic venous collateralization is frequent after the construction of a bidirectional cavopulmonary shunt. This may worsen hypoxemia by reducing the effective pulmonary blood flow and by connections to the pulmonary vein or left atrium.
- There are concerns about the growth of the pulmonary arteries after the bidirectional cavopulmonary shunt.
- When hepatic venous blood is excluded from the pulmonary circulation, pulmonary arteriovenous fistulae are a likely consequence.
- Pulmonary arteriovenous fistulae may be a universal consequence of the bidirectional cavopulmonary shunt.
- The development of pulmonary arteriovenous fistulae and the relationship to hepatic venous blood is a paradigm for bed-to-bench research.
- The cavopulmonary shunt increases effective pulmonary blood flow without volume-loading the ventricle.
- Ventricular volume unloading has the potential to improve the severity of atrioventricular valve regurgitation.
- Ventricular volume unloading may lead to a change in ventricular size and geometry in patients with a dominant left ventricle, rudimentary right ventricle and transposition of the great arteries, resulting in systemic outflow tract obstruction.[139,140,207,208]

The Fontan–Kreutzer Procedure

It seems a natural evolution from the partial right heart bypass, the classical Glenn or cavopulmonary shunt (see Chapter 35), to the complete right heart bypass as conceived and performed by Fontan of Bordeaux in 1968, and published with Baudet in 1971 (Fig. 36-1).[1,1A] Kreutzer of Buenos Aires almost simultaneously devised a similar procedure for the patient with tricuspid atresia.[2] Most involved with the care of children with congenital heart disease consider these contributions as one of the signal achievements in the last half of the 20th century for patients whose cardiac malformations are not amenable to biventricular repair.[3] Since this procedure was first performed in 1968 on the patient with tricuspid atresia, the procedure or any of its many modifications have been applied to a wide variety of congenitally malformed hearts not amenable to biventricular repair.[4] Indeed, some have used this procedure preferentially over a high-risk biventricular repair.[5] Throughout the early to late 1970s and well into the 1980s there was an exponential increase in publications devoted to virtually all aspects of the Fontan procedure, in the more recent era addressing surgical modifications and outcomes. In order to provide selection guidelines for the performance of the Fontan procedure, Choussat and his colleagues provided in 1978 a number of criteria for those considering this operation.[6] These criteria have been scrutinized and modified over the years in order to optimize outcome by reducing early and late Fontan mortality and morbidity. As one surveys the substantial literature that has addressed outcomes of the Fontan procedure over the past three decades, early mortality has continued to decrease and Kaplan–Meier survival curves suggest improved survival. It is difficult to define any single strategy that has enhanced outcome as the entire "platform" for congenital heart surgery has improved over this time frame. Furthermore, other maneuvers have been introduced including staging with a bidirectional cavopulmonary shunt and fenestration, in order to reduce mortality in so-called high-risk patients. In this chapter, we will review the original criteria as proposed by Choussat and colleagues and comment on those other innovative strategies. The Kawashima operation used in patients with complex congenital heart disease with interrupted inferior vena cava and its sequelae are discussed in Chapter 35. The original criteria proposed by Choussat are listed in Table 36-1.

In consideration of these original criteria as set out by Choussat and his colleagues, Graham and Johns pointed out that the following issues or criteria were not included or considered in the 1978 publication:[7]

- diastolic dysfunction
- ventricular hypertrophy
- systemic outflow tract obstruction
- right ventricular type of single ventricle.

One risk factor not addressed either by Choussat and his colleagues, or by Graham and Johns was the issue of extensive systemic aortopulmonary collateral arteries derived from the descending thoracic aorta, or subclavian artery or its tributaries, or both.[8–12A] Another new indicator that has been proposed is the diameter of the pulmonary veins in patients with univentricular hearts.[13]

Age 4–15 years

There is not unanimity as to the optimum age to perform the Fontan operation.[4,14–24] Certainly the operation can be carried out in children as young as two years of age or younger and in adults as well with excellent results. When the operation was performed in patients < 2 years of age, many times these particular patients were already considered at some risk for later exclusion from the Fontan. When patients at this age met the critieria for a Fontan procedure, the outcome was similar. Thus younger age in itself does not seemingly jeopardize the outcome for the Fontan procedure. Excellent results have been published for the older patient undergoing Fontan's operation as well.[20,21,23]

Normal right atrial size

In the early days of the Fontan experience, a large, thin-walled right atrium was considered a potential risk factor (Fig. 36-2).[6] It was felt that whatever "pump" function the right atrium contributed to Fontan hemodynamics would be lost in the original atriopulmonary connection. Whether this was true or not, the concern about right atrial form and function has been obviated by the evolution in surgical technique (Table 36-2) (Figs 36–1 to 36-5).

The contribution of de Leval and his colleagues with the total cavopulmonary connection is important to the history and indeed success of the Fontan strategy.[25] As stated in this paper published in 1988, the total cavopulmonary connection has the following advantages: they are technically simple and reproducible in any atrioventricular arrangement; the surgical connections are relatively distant from the atrioventricular node; most of the right atrium remains at low pressure reducing the risk for early and late rhythm disturbances; and reduction of turbulence in the enlarged right atrium prevents energy losses and hopefully should minimize the risk of atrial thrombosis. This

lateral tunnel form of total cavopulmonary bypass set the stage for extracardiac Fontan.

Normal sinus rhythm

Numerous studies have demonstrated excellent early survival in patients not in sinus rhythm undergoing the Fontan procedure.[4,15–19,23,26] There has been the suggestion that patients with complete heart block before the Fontan despite pacing do not fare as well, but that has not been our experience (acknowledging only a small patient population with heart block undergoing a Fontan operation).[23] Clinical experience does suggest that patients who are not in sinus rhythm before the Fontan operation are more likely to experience supraventricular dysrhythmias, both early and late, after the procedure.[26–35]

Table 36-1 Criteria for Fontan's operation

Age 4–15 years
Sinus rhythm
Normal drainage of caval veins
Normal volume of right atrium
Normal pressure ≤ 15 mmHg
Pulmonary resistance < 4 U/m^2
Ratio PA : AO ≥ 0.75
Normal ventricular function
No mitral insufficiency
No impairing effect of shunt

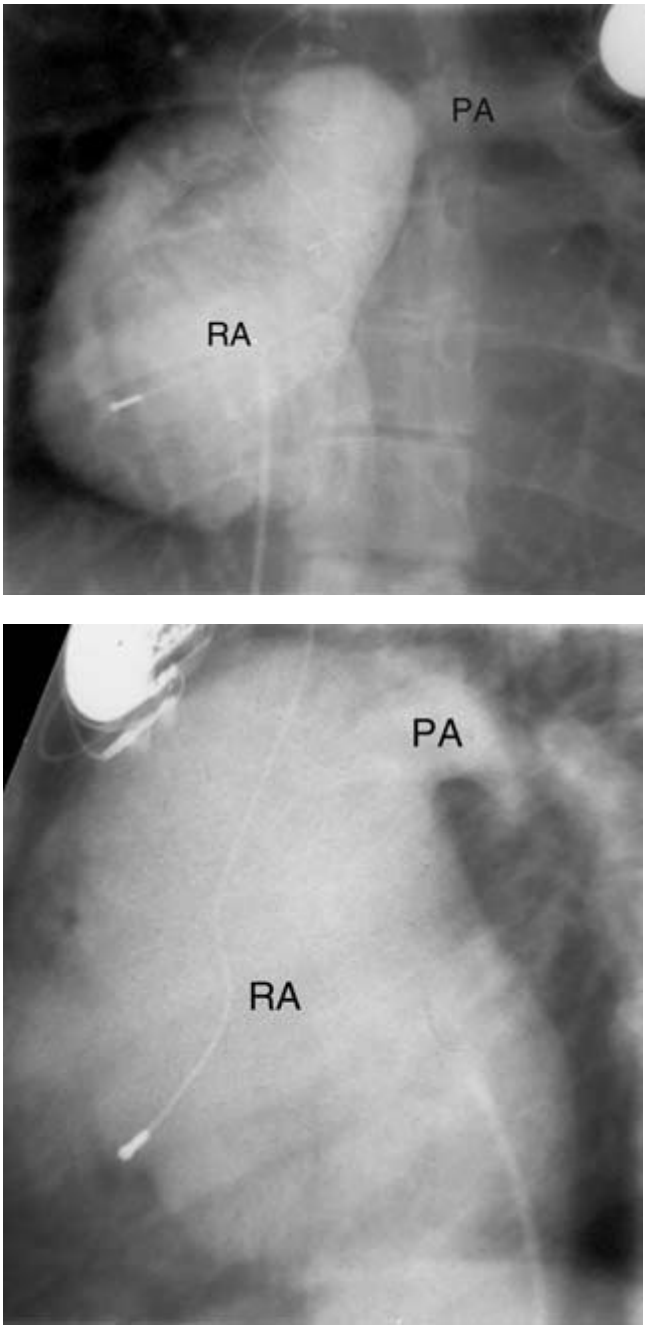

Fig. 36-2 Severe dilatation of the right atrium (RA) after classical Fontan operation. PA, pulmonary artery.

*Not necessarily listed by primacy of report.

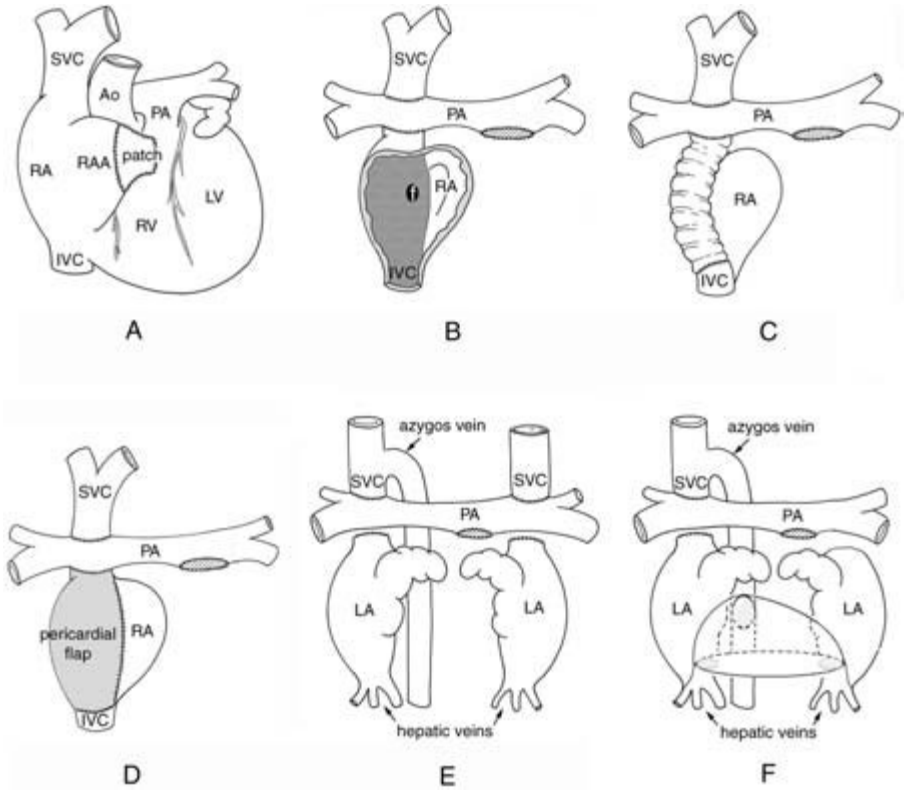

Fig. 36-3 Modifications of Fontan operation. **A**. Bjork's modification: for patients with a small but functioning right ventricle as in tricuspid atresia, a connection is made between the right atrial appendage (RAA) and the right ventricular outflow tract. **B**. Total cavopulmonary connection(TCPC): the divided superior vena cava (SVC) is anastomosed to the right pulmonary artery. The inferior vena cava (IVC) is tunneled along the right atrial wall using a tubular graft opened longitudinally and anastomosed just anterior to the right pulmonary veins posteriorly. Anteriorly the graft is closed to the two edges of the atriotomy incision. This variant has some growth potential. A fenestration (f) can be made. **C**. Extracardiac Fontan: a tubular graft (PTFE or allograft) is connected to a cuff of right atrium above the IVC, and top the inferior surface of the confluent pulmonary arteries. This operation can be done without opening the heart, and in some patients without cardiopulmonary bypass. **D**. Growing extracardiac lateral tunnel: a pericardial flap is sutured to the external surface of the right atrium to create a tubular connection between both cavae and the pulmonary arteries. This variant has some growth potential. **E**. Kawashima operation: for patients with azygos continuation of the IVC to a right (or left) superior vena cava, connection of the superior vena cava to the pulmonary artery (as for a bidirectional cavopulmonary anastomosis) diverts all but the hepatic blood flow into the pulmonary circulation. These patients are at high risk of developing pulmonary arteriovenous fistulae and must have their hepatic flow connected to the pulmonary circulation either at the time of the Kawashima operation or soon thereafter. One option for hepatic vein diversion is an end to side anastomosis with the azygos vein (**F**). Ao, aorta; f, fenestration in the lateral tunnel; IVC, inferior vena cava; LA, left atrium; PA, pulmonary artery; RA, right atrium; RAA, right atrial appendage; RV, right ventricle; SVC, superior vena cava.

Normal caval and pulmonary venous connections

In the earlier eras of Fontan surgery, patients with visceroatrial heterotaxy seemingly had a higher Fontan mortality. The reasons for this were certainly multifactorial, but one could assign risk to the often frequent abnormalities of systemic and pulmonary venous return,[36–41] as well as to the regurgitant atrioventricular valve. Any abnormal resistance posed by anomalously connected pulmonary veins had to be dealt with and this clearly prolonged the operation.[36–41] In some patients complex atrial baffles had to be constructed to completely separate the systemic from the pulmonary venous connections. The introduction of the bidirectional cavopulmonary connection or the hemi-Fontan as an intermediate step in single ventricle palliation served to neutralize these particular issues[42–54] (see also Chapter 35). It is at the time of the bidirectional cavopulmonary connection that specific anomalies of systemic and pulmonary venous connections are addressed. Furthermore, pulmonary arterial stenosis resulting from a previously constructed systemic-to-pulmonary arterial shunt or from "normal" ductal closure can also be repaired at this time.[55] Systemic outflow tract obstruction shown throughout the Fontan experience to be a risk factor for mortality could be neutralized at this staging and intermediate operation by either enlarging the often restrictive ventricular septal defect, or by constructing a proximal pulmonary artery-to-ascending aortic connection, the Damus–Kaye–Stansel procedure.[56–75]

Normal PA pressure and pulmonary vascular resistance

Surgical mortality at the time of the Fontan procedure has been stratified against pulmonary vascular resistance and it is evident that pulmonary vascular resistance be calculated at cardiac catheterization. This is of course easier in principle than in reality. The occurrence of pulmonary artery stenosis, multiple sources of pulmonary blood flow (from one or more previously constructed shunts as well as from aortopulmonary collaterals),

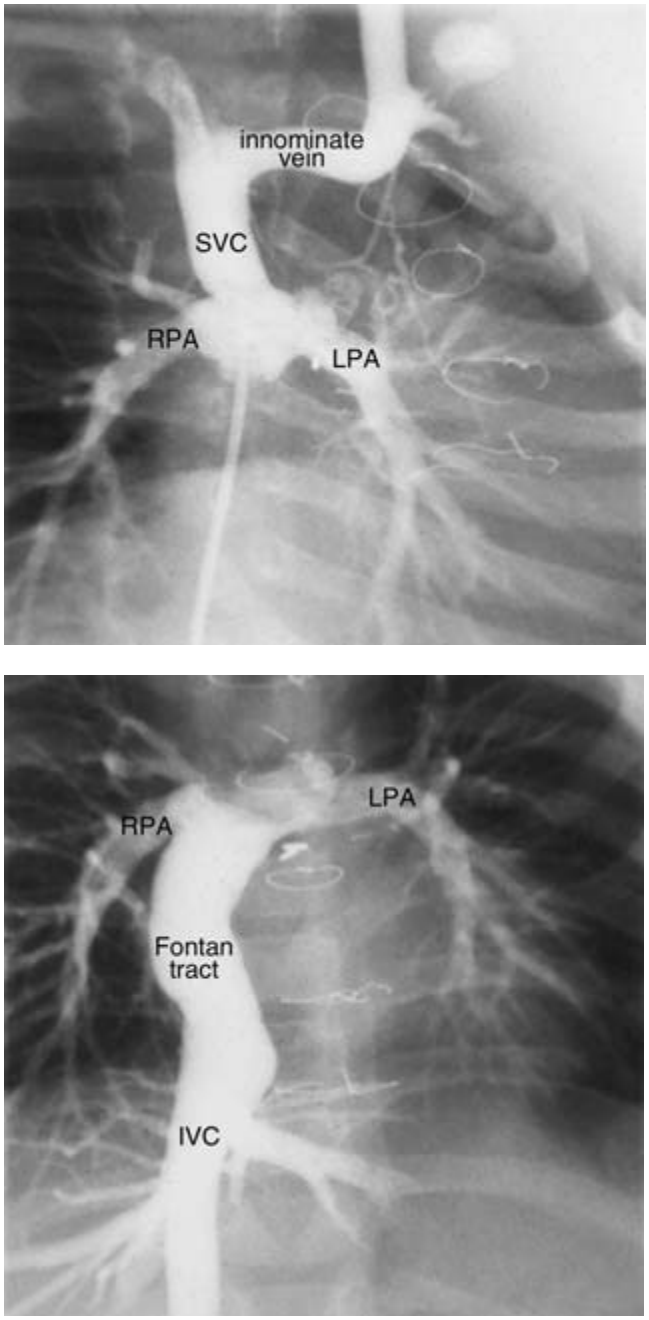

Fig. 36-4 Total cavopulmonary anastomosis with intracardiac lateral tunnel. Injections into the innominate vein (**A**) and Fontan tract (**B**) show unobstructed connections and pulmonary arteries. IVC, inferior vena cava; LPA, left pulmonary artery; RPA, right pulmonary artery; SVC, superior vena cava.

pulmonary arteries of disparate size, non-confluent pulmonary arteries as in those patients previously treated with classic unilateral cavopulmonary connection make that calculation frequently difficult and fraught with assumptions.[76,77] Data from the Mayo Clinic shown in Tables 36-3 and 36-4, demonstrate increased surgical mortality, early and late, when mortality is stratified against increasing pulmonary vascular resistance alone (Table 36-3)[77] or a against a score including indexed pulmonary vascular resistance and left ventricular diastolic function (Table 36-4).[78]

Data from the Mayo Clinic addressing mortality in terms of pulmonary vascular resistance are shown in Table 36-3.[77]

Using the indexed score from the Mayo Clinic that attempts to incorporate some aspect of diastolic function, the following data is shown in Table 36-4.[78]

The ability to apply this index requires one to measure pulmonary blood flow, and as mentioned earlier that may prove difficult. In addition, oxygen consumption should be measured, not assumed, for these calculations to have any significance. Modest differences in indexed pulmonary vascular resistance may have a minimal effect on the outcome of patients undergoing a biventricular repair (i.e. ventricular septal defect, etc.). However, for patients undergoing a Fontan-type operation the outcome

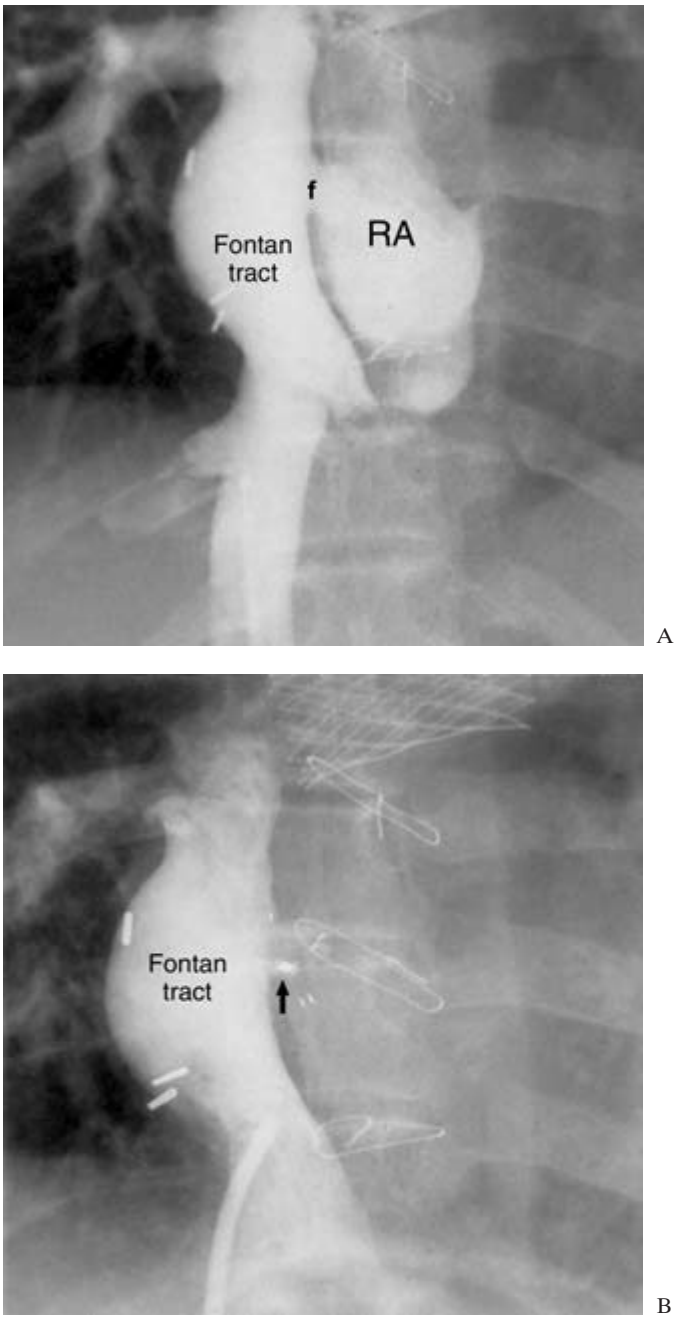

Fig. 36-5 Fenestrated Fontan operation. **A**. Injection into the Fontan tract demonstrates a fenestration (f) in the partition between the lateral tunnel and the rest of the right atrium (RA). **B**. The fenestration was closed by placing a Rashikind occlusion device.

Table 36-3 Relationship of preoperative pulmonary resistance and mortality in patients with double-inlet left ventricle

	Mortality (%)	
Resistance (U/m^2)	Early	Overall
< 2.0	3	15
21–3.0	11	44
3.1–4.0	50	50

may be considerably worse with only a modest increment in pulmonary vascular resistance.

Pulmonary artery size (PA/AO ≥ 0.75)

Choussat and his colleagues suggest that the diameters of the pulmonary arteries when compared to the aortic diameter should be ≥ 0.75.[6] It would seem logical that patients with larger rather than smaller pulmonary arteries would have a better outcome of Fontan's operation as blood is conveyed into the lungs without a pump. Indeed, some, but not all, agree that pulmonary size as indexed to a variety of standards is necessary for a successful outcome at Fontan's operation.[79–82] But there is debate as to exactly what surface area of the pulmonary arteries is adequate or ideal for Fontan repair. Whether one uses the McGoon ratio, the Nakata index, or some amalgam thereof, these measurements of the caliber of the central pulmonary arteries do not provide information about the compliance of the pulmonary vascular bed.[83–86] The McGoon ratio is determined by summing the diameter of the immediately prebranching portion of the right and left pulmonary artery and dividing this sum by the diameter of the descending aorta at the level of the diaphragm, all the measurements being taken in systole.[83–85] When this ratio was as low as 1.2, the probability of death or takedown of the Fontan within 30 days of operation was 55% for an atriopulmonary connection.[79] The Nakata index or pulmonary artery index is determined by measuring the diameters of the right and left pulmonary arteries immediately proximal to the origin of the first lobar branches; the cross-sectional areas were then calculated, summed and divided by the body surface area.[86] The resulting value is called the pulmonary artery index. Nakata and his colleagues applied this index retrospectively to 15 patients undergoing Fontan's operation and based on 3 deaths in this small series concluded that the Fontan procedure should be reserved for those patients with a pulmonary artery index ≥ 250 mm^2/m^2.[86] In 1985, Girod and his colleagues correlated pulmonary artery index with operative mortality in 90 patients undergoing a modified Fontan operation.[87] They found no significant difference in mortality between those with an index > 250 mm^2/m^2 or in those with an index < 250 mm^2/m^2.[87] In this study survival was achieved in some patients with an index as low as 188 mm^2/m^2. Bridges and her colleagues also found the Nakata or pulmonary artery index to be a non-predictor of operative survival in patients undergoing the Fontan procedure.[80] Although the range of the pulmonary artery index in the Bridges' study differs from that published several years earlier by Girod,[87] their conclusions are the same. One should not be surprised by these results, because as Bridges and her colleagues point out, the greatest contribution to pulmonary vascular resistance comes from the precapillary arterioles, with the next most significant contribution from the postcapillary venules.[80] Data have been provided by Knott-Craig and his colleagues from the Mayo Clinic who also measured the pulmonary artery index of 173 patients undergoing Fontan's operation.[82] They were unable to define a lower limit of this index compatible with a successful outcome. Yet their data seemed to indicate that small pulmonary arteries in otherwise good-risk patients was associated with increased risk of "early failure or persistent effusions."[82] Senzaki and his colleagues have also studied the influence of pulmonary artery size on postoperative hemodynamics of the Fontan operation.[81] They calculated both the pulmonary artery index using the Nakata methodology and pulmonary vascular compliance. They did not find a correlation between the pulmonary artery index and pulmonary vascular resistance, but they did find a significant correlation between the pulmonary artery index and pulmonary vascular compliance.[81] They found that pulmonary vascular compliance influenced postoperative hemodynamics of the Fontan operation by affecting peak central venous pressure and total impedance. From their data, smaller pulmonary artery size promotes the disadvantages of the hemodynamics of the Fontan operation with a resultant rise in peak central venous pressure and increased afterload to the single ventricle. Lung biopsy, once advocated by some as possibly one arbiter, is now rarely indicated in the preoperative management of the patient considered for Fontan surgery.[88–90] Some, however, suggest that nitric oxide synthase expression by pulmonary arteries may be a predictive marker of Fontan outcome.[89] In a small retrospective study Levy and colleagues found in lung biopsy material a clear endothelial nitric oxide synthase overexpression in patients in whom the Fontan operation failed. As is well known, pulmonary arterial stenosis or stenoses impose an untenable impedance to Fontan hemodynamics and for this reason, such obstructive lesions must be adequately dealt with either before or at the time of the Fontan (Fig. 36-6). In this regard, Fontan operations have been carried out in patients with a single lung.[81A,B,C] Most of these series are small, but when the patients are carefully selected, the risk does not appear appreciably higher. Similarly, the Fontan operation has been performed successfully after reconstruction of non-confluent pulmonary arteries.[81D] Finally, Kawahira *et al*. suggest that the diameters of the pulmonary veins in patients with univentricular heart should be a new indicator for patients considered for the Fontan operation.[13] The diameters of the pulmonary veins are measured proximal to the entrance into the atrium from the late phase of a pulmonary arteriogram. The pulmonary vein index is calculated from the sum of the cross-sectional areas of these veins divided by the body surface area. For patients undergoing a successful bidirectional cavopulmonary shunt, the pulmonary vein

Table 36-4 Mortality at Fontan procedure stratified by preoperative catheterisation index

R_P (U/m^2) + LVEDP/(Q_{P1} + Q_{S1})	Early and late mortality (%)
1.1–2.0	5
2.1–3.0	6
3.1–4.0	14
4.1–5.0	27
≥ 5.0	57

(From Mair *et al.*[78] with permission.)

index was 361 ± 153 mm^2/m^2 and for those whose outcome was poor, the pulmonary vein index was 275 ± 60 mm^2/m^2 ($P = 0.03$). Of their patients undergoing a successful Fontan procedure, the pulmonary vein index was > 275 mm^2/m^2 and for the unsuccessful Fontan, 137 mm^2/m^2. This group also calculated a "new" pulmonary vascular resistance (PVR): "new" PVR = 100 × (mPAP – mAP)/pulmonary vein index where mPAP and mAP are the mean pulmonary artery and atrial pressures respectively.[13] The "new" PVR value for those patients undergoing a successful Fontan procedure was < 2.0 $mmHg/mm^2$ per m^2 while that for an unsuccessful result was 4.4 $mmHg/mm^2$ per m^2. The concern about pulmonary vein size as a possible risk factor for poor Fontan outcome is certainly predicated in part by the observations of Jenkins and Heineman and their respective colleagues who studied pulmonary vein caliber in patients with heterotaxy.[91,92]

Normal ventricular function

It would be anticipated that Choussat and his colleagues list normal ventricular function as one of the tenets in consideration of Fontan's operation.[6] But what is "normal" ventricular function for a patient with a univentricular atrioventricular connection? Physicians caring for patients considered candidates for Fontan's operation have been concerned about the lower limits of ventricular function (systolic ejection fraction, shortening fraction, etc.) for a satisfactory outcome of this procedure. Ventricular function parameters for patients with a dominant left ventricle have been compared to the functional equivalent of the left ventricle in a biventricular situation and similar methodologies have been used for the patient with a dominant morphologically right ventricle. There are obviously important assumptions to all these determinations. Contractile or ventricular function has been assessed using a variety of methodologies before and following the Fontan procedure as has regional wall motion.[7,93–104] Graham and Johns suggest that patients considered for Fontan's operation should have a ventricular ejection fraction ≥ 50%, but in those with even lower ejection fraction data, an estimate of end-systolic stress and contractile state should be made.[7] It is also well known that some patients may have a marked increase in afterload which may lead to a decrease in ejection fraction. Since afterload can decrease after a Fontan operation, some patients with a borderline or frankly low ejection fraction may in fact still be candidates for Fontan's operation.[7] There is not unanimity as to the most meaningful methodology to ascertain diastolic function and ventricular compliance. If the ventricular end diastolic pressure is >12 mmHg and there is not conspicuous volume loading, then one should be concerned about the wisdom of performing a Fontan procedure. Yet, no single factor or "number" should automatically exclude a patient from consideration for Fontan completion. Contractile function can be anticipated to recover in some patients with "single" left ventricle after conversion to a Fontan circulation.[98] In the echocardiographic study of Sluysmans and colleagues ventricular volumes in patients with double-inlet left ventricle and tricuspid atresia before the Fontan were two to three times normal.[98] In patients < 10 years of age converted to either a Glenn or Fontan circulation, ventricular dimensions, volumes and wall stress all diminished and left ventricular function and contractility improved after surgery. In those undergoing surgery > 10 years of age, few demonstrated improvement in left ventricular function. Indeed, postoperative ventricular function and contractility were inversely related to age and to aortic saturation measured before surgery. Any number of studies have shown that regional wall motion abnormalities are common in univentricular hearts. Kurotobi and colleagues suggest that such ventricular systolic abnormalities are caused by the rudimentary right ventricle.[99] In their study, the rudimentary right ventricle caused a regional wall abnormality which resulted in asynchronous contraction of the main or dominant ventricular chamber. There are certainly factors other than the rudimentary right ventricle as indicated earlier that may depress or alter regional contractile function including a primary alteration in the arrangement of ventricular fibers, abnormal ventricular conduction, myocardial fibrosis from chronic volume and/or pressure overload, etc. These authors go on to suggest that the rudimentary right ventricle which is usually at systemic pressure affects the regional wall motion in the corresponding area of the dominant ventricle through the direct effects of a second high pressure chamber.

The relationship between diastolic function, ventricular hypertrophy and ventricular compliance is complex and not easy to calculate. There is considerable clinical experience that ventricular hypertrophy is a risk factor for poor outcome of a Fontan procedure.[56–71] Graham and Johns suggest that patients with a ventricular mass > 200% of predicted are at increased risk for Fontan procedure.[7] Others have related wall mass to ventricular end-diastolic volume as a possible index to use in this assesment,[64–66] and virtually all of these studies condemn abnormal ventricular hypertrophy as an important risk factor. Kirklin and his colleagues suggested > 15 years ago that ventricular hypertrophy was a risk for early mortality at Fontan's operation and that such ventricular hypertrophy was an inevitable consequence of aging and as well a consequence of systemic outflow tract obstruction.[19] The most common clinical situation where hypertrophy is an important concern for the patient considered for a Fontan operation is the anatomical sub-

strate of a dominant left ventricle, a rudimentary right ventricle, discordant ventriculoarterial connections, and a previously banded pulmonary artery trunk.[56–71] The ventricular septal defect in this situation is usually smaller than the aortic root, and thus intrinsically predisposed to disadvantageous diminution in size or closure.[57,61,105,106] Further volume reduction from banding the pulmonary trunk and myocardial hypertrophy from increasing the ventricular afterload all contribute to further diminution in size of the ventricular septal defect and systemic outflow tract obstruction.[59–66] These factors contribute to a disadvantageous wall mass/end-diastolic volume ratio. Patient outcomes reported from the Mayo Clinic, Toronto and elsewhere all provide evidence as to the egregious effects of systemic outflow tract obstruction and its consequence, ventricular hypertrophy, on outcomes.[19,56–63,65,67] This factor has been effectively neutralized by staging with a bidirectional cavopulmonary shunt and addressing the mechanism of the systemic outflow tract obstruction. Hiramatsu and colleagues have reported their excellent results of the surgical treatment of 25 patients with systemic ventricular outflow tract obstruction in Fontan patients.[106A] Twenty-one patients had undergone prior pulmonary artery banding and 10 patients had undergone prior arch repair. Systemic ventricular outflow obstruction progressed in 5 patients after the Fontan procedure. The mean age at operation was 6.5 years and the average preoperative pressure gradient across the ascending aorta and systemic ventricle was 29 mmHg (range 0 to 100 mmHg). The Damus–Kaye–Stansel procedure was performed in 18 patients (double-barrel anastomosis in 13, end to side anastomosis in 5), and subaortic resection or ventricular septal defect or bulboventricular foramen enlargement was performed in 7. A double-barrel anastomosis has been their first choice since 1994, if the pulmonary valve is intact. Follow-up ranged from 4 months to 14 years (average 5.0 years). Twenty-three of the 25 patients have undergone recatheterization (average 21.4 months later). No early deaths were found; 1 late death was reported of a patient with single right ventricle (4.0%). The postoperative average pressure gradient was 1.1 mmHg (0–10 mmHg), and the average right atrial pressure was 14 mmHg (9–20 mmHg). In all patients who underwent ventricular septal defect or bulboventricular foramen enlargement, regular sinus rhythm was maintained postoperatively. Regarding the Damus–Kaye–Stansel procedure, there was minimal progression of semilunar valve insufficiency except in 1 patient who underwent end-to-side anastomosis with moderate pulmonary regurgitation postoperatively. Clearly these results are excellent and depart from the experiences of other centers where staging provided better outcomes.

Decreased ventricular performance and increased muscle mass and dimension have been found in unrepaired and palliated patients with a "single" left ventricle.[7] Gewillig and his colleagues found a significant increase in ventricular wall thickness, particularly in diastole, immediately after a Fontan operation.[95] Some months after the Fontan operation, these parameters seemed to normalize in these patients. Penny and Redington and their colleagues have described incoordinate motion of the ventricular wall after the Fontan operation resulting in abnormal systolic atrioventricular flow.[107–110] These authors have also demonstrated abnormal patterns of intraventricular flow and diastolic filling after the Fontan operation which they suggest is also evidence for incoordinate motion of the ventricular wall. There are implications of these observations for diastolic filling, pulmonary blood flow and cardiac output in the Fontan patient. Thus there is considerable remodeling of the single ventricle after a modified Fontan procedure (see Table 36-5).

Table 36-5 Systemic ventricular remodeling after the Fontan operation

Reduction in end-diastolic volume
Increase in ventricular wall mass (i.e. mural wall thickness)
Marked changes in diastolic function
Altered filling pattern
Prolongation of time constant of relaxation
Incoordinate ventricular relaxation
Abnormal systolic atrioventricular flow
Possible increased myocardial stiffness

Does ventricular morphology impact on the outcome of a Fontan operation? Kirklin and his colleagues did not find ventricular morphology of the dominant ventricle as an incremental risk factor for death after a modified Fontan operation.[19] Yet Gentles and Matsuda and their respective colleagues and an earlier paper from the Mayo Clinic suggest that right ventricular morphology adversely affects outcome.[23,40] Julsrud and his colleagues from the Mayo Clinic in a comprehensive review found that ventricular morphology is a risk factor for early survival in patients undergoing a Fontan procedure, with left ventricular morphology associated with a better early survival than right ventricular morphology.[111,112] Kawahira and colleagues have asked whether the patient with a double-inlet morphologically right ventricle vs. other types of double or common inlet ventricle had a different Fontan outcome.[113] This group compared the outcome of 31 patients with double-inlet right ventricle, 45 with double-inlet left ventricle, 93 with common-inlet right ventricle, and 20 with common-inlet left ventricle. Pulmonary atresia was found in 58% of the patients with double-inlet right ventricle, and pulmonary atresia with non-confluent pulmonary arteries in 15%, both situations much more common in this series than in the patient with a double-inlet left ventricle. Twenty-one patients (68%) with a double-inlet right ventricle underwent the Fontan procedure, compared with only 37% of those with a common-inlet right ventricle. Survival rate after the Fontan in patients with double-inlet right ventricle was 95% at 10 years, nearly the same as for the patient with double-inlet left ventricle. The Kaplan–Meier survival curves were statistically better in the patients with either a double-inlet left ventricle or double-inlet right ventricle when compared to either ventricular morphology with a common-inlet.[113] It is not unexpected that atrial isomerism was identified in 36% of patients with a double-inlet right ventricle, 4% with a double-inlet left ventricle; 93% of those with a common-inlet right ventricle and 90% of those with a common-inlet left ventricle.[113] An abnormal myoarchitecture and increase in connective tissue has been described in hearts with tricuspid atresia.[114] The effect of this finding on cardiac performance has yet to be determined.

No regurgitation of the systemic atrioventricular valve

Important regurgitation of the systemic atrioventricular valve was identified as a risk factor for poor outcome and late mor-

tality and morbidity after a Fontan procedure.[6,15,23,27,36–41,115–117] The bidirectional cavopulmonary shunt unloads the ventricle and in some children where the primary mechanism responsible for the AV valve regurgitation was annular dilatation, improvement in the functionality of the valve was seen.[48–54,118–122] Unfortunately, many patients continued to have important atrioventricular valve regurgitation despite ventricular unloading procedures. Imai, his colleagues and others have published impressive series of patients undergoing annuloplasty/valvuloplasty either at the time of the bidirectional cavopulmonary shunt or Fontan procedure with gratifying results.[123–125] The complex atrioventricular valve morphology seen in patients with right isomerism does not lend itself to standard reparative procedures, and some have resorted to so-called endocardial cushion prosthesis in these difficult experiences. Most centers have some experience with the replacement of an atrioventricular valve either at the time of the bidirectional cavopulmonary shunt or at the Fontan itself.[126]

Systemic aortopulmonary collateral arteries

A number of studies have suggested that systemic aortopulmonary collateral arteries pose a risk factor for Fontan outcome, both in terms of mortality and morbidity.[8–12,27] There is some evidence that prolonged pleural effusions occur more commonly in those with substantial aortopulmonary collateral arteries. Thus it has become incorporated into our therapeutic algorithm that at the pre-Fontan catheter investigation important collateral vessels, both arterial and venous, be occluded with coils or other devices. Yet there is certainly ongoing discussion as to the significance of aortopulmonary collateral arteries. The experience of Kanter and Vincent would suggest that patients with extensive aortopulmonary collateral arteries fare poorly at and after Fontan surgery,[9,9A] an experience not shared by Bradley.[12,12A]

Staging and fenestration

Two maneuvers have been introduced to reduce mortality and morbidity in so-called high risk Fontan patients. Both maneuvers have been incorporated into the surgical algorithms for patients undergoing single ventricle palliation. These maneuvers are the interposition of the bidirectional cavopulmonary shunt (see Chapter 35) between initial palliation and the modified Fontan procedure itself and the fenestrated Fontan.[18,23,41–54,119–123] In the previous chapter we considered the role of the bidirectional cavopulmonary shunt as a staging maneuver, a maneuver usually combined with repair of risk factors for poor outcome of Fontan's operation, including pulmonary arterial stenosis, atrioventricular valve regurgitation, and systemic outflow tract obstruction. There is considerable clinical evidence that this staging maneuver provides excellent palliation for the infant or young child and that the bidirectional cavopulmonary shunt provides equivalent survival to a Fontan procedure.[127] The only caveat is that the adult is usually not effectively palliated by a bidirectional cavopulmonary shunt when this is the sole source of pulmonary blood flow,[128] reflecting the disadvantageous ratio between upper and lower systemic venous return.[129] There is less agreement as to whether an additional source of pulmonary blood flow is advantageous or not (see Chapter 35). In terms of conveying hepatic venous effluent into the lungs and minimizing the risk for pulmonary arteriovenous malformations, there may be some advantage to an additional source of forward ventricular flow (see Chapters 35 and 37).

What is the advantage to fenestrating the Fontan circulation?[130] Doesn't this defeat the purpose of effectively separating the systemic venous return from the pulmonary venous return? As Jonas stated in 1994, the Children's Hospital in Boston added the bidirectional cavopulmonary shunt in 1988 as an interim step for patients then considered to be at high risk for the Fontan, namely the patient with the hypoplastic left heart syndrome.[43] In 1989, this group added the fenestration to Fontan completion. The placement of a communication in the partition between the systemic and pulmonary venous circulations as an integral part of the Fontan operation results in lower superior and inferior caval venous and right atrial pressures.[43,131–135] Arterial oxygen saturation is lower, about 88% to 90%, but cardiac output is higher. This maneuver seemingly reduces the severity and duration of postoperative pleural effusions and the length of hospital stay as shown in at least one prospective, randomized study.[134A] Another disadvantage of fenestration is the increased risk for paradoxical systemic venous embolization to the central nervous system and other systemic organs. Clearly non-fenestration does not eliminate the possibility of stroke, etc. While fenestration was initially employed for the patient considered high risk for a Fontan procedure, many now routinely fenestrate all, or virtually all Fontan patients. One could then ask whether routine fenestration is justified. This question was posed by Airan and colleagues who found that elective fenestration of the intraatrial baffle was associated with decreased Fontan failure rate and decreased occurrence of significant postoperative pleural effusions.[136] Their conclusion was that routine elective fenestration of the atrial baffle is justified in all univentricular repairs. Hsu and her colleagues from Columbia University reported an excellent outcome after the single-stage non-fenestrated Fontan procedure in 61 patients.[137] Three of the 61 patients (4.9%) died in the early postoperative period. Of these 61 patients, 20 (33%) had no preoperative risk factors and were considered ideal candidates for a single-stage non-fenestrated Fontan. Forty-one patients (67%) had one or more risk factors and two or more risk factors were present in 23% of the patients. This group concluded that routine baffle fenestration is not indicated in a large cohort of patients with single ventricle physiology.[137] Thompson and his colleagues asked the same question for patients undergoing an extracardiac Fontan and arrived at basically the same conclusion.[138] For those who have fenestrated the Fontan, spontaneous closure of the fenestration has been well documented. Bando and his colleagues found that when the fenestration was 2.5 mm, 90% closed spontaneously within one year of surgery, while only 64% of 4.0 mm fenestrations spontaneously closed.[139] Similar results have been reported elsewhere.[140]

Fontan outcomes

In this chapter we have examined the classic guidelines for the performance of the Fontan operation or any of its modifications. Some of the initial guidelines have been obviated by evolution in surgical technique, while for others, the issues remain complex and confusing. As we have discarded some of the original criteria, we have added new criteria. But these new parameters are also complex and difficult to quantitate. What and how many risk factors should be used to include or exclude a patient from the Fontan operation? What candidates for Fontan's oper-

ation are considered high risk? Is risk based on anatomy, physiology, or some combination thereof? Yoshimura and colleagues in 2001 state that "patients with complex cardiac anomalies who have six or more risk factors should be excluded from total cavopulmonary connection candidates."[141] What is the optimum surgical technique,[142] the lateral tunnel Fontan operation as advocated by the Children's Hospital of Boston,[143] the extracardiac conduit, currently favored by Toronto or San Francisco,[144,145] or a growing extracardiac lateral tunnel with pedicled pericardium as advocated by the Loma Linda group?[146] Van Arsdell and the Toronto group have identified those interventions associated with minimal Fontan mortality.[147] The operative mortality for the first 400 Fontan procedures at the Toronto Hospital for Sick Children was 15%, and it declined to 4% for the next 100 procedures (Fig. 36-7).[147] Patient characteristics and risk factors were similar in the two groups. The extracardiac Fontan procedure and modified ultrafiltration after bypass were associated with lower mortality, and each of these had the potential to improve postoperative myocardial function. Knott-Craig and his Mayo Clinic colleagues reviewed their entire experience with 702 consecutive patients who had the modified Fontan operation at the Mayo Clinic between October 1973 and December 1989 to better understand risk factors associated with early postoperative death or failure.[15] The event rate for takedown of repair or death during the initial hospitalization or within 30 days of the operation was 14.8% (successful takedown of the repair, $n = 6$; death, $n = 98$). To identify variables associated with early death or Fontan takedown, they analyzed 33 clinical and hemodynamic variables in a univariate and multivariate manner. On the basis of a stepwise logistic discriminant analysis, patients who were younger and operated on before 1980 with a higher preoperative pulmonary artery mean pressure, asplenia, higher intraoperative (after Fontan operation) right atrial pressure, longer aortic crossclamp time, and pulmonary artery ligation were more likely to have the outcome event of interest ($P < 0.05$). A new variable, corrected pulmonary artery pressure (that is, mean preoperative pulmonary artery pressure divided by the ratio of pulmonary to systemic flow if the ratio of pulmonary to systemic flow is > 1.0), was significantly associated with the outcome event univariately ($P = 0.002$), but was no more predictive than the preoperative pulmonary artery mean pressure. Variables less predictive of the outcome event in this analysis included multiple prior operations, polysplenia syndrome, complex anatomy other than asplenia syndrome, and systemic atrioventricular valve regurgitation.

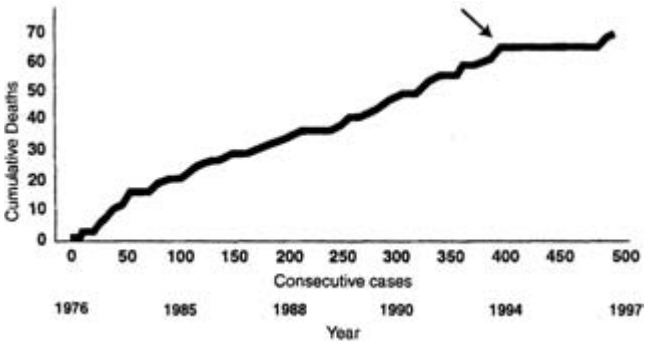

Fig. 36-7 Graph showing cumulative summation of patient mortality for Fontan procedure. There were 67 deaths among 500 patients, a mortality of 13.4%. The arrow points to an inflective point in the slope of the mortality curve. (Reprinted from Van Arsdell *et al.*,[147] Copyright (2000), with permission from The Society of Thoracic Surgeons.)

Surgical results and short-to-midterm outcomes have certainly improved over the eras after a modified Fontan procedure.[148–155] None the less, the reality is that it is unlikely that any form of Fontan operation will provide a Kaplan–Meier survival curve equivalent to that of a normal population. Indeed, there is no such thing as a perfect Fontan.[24]

Many reports of Fontan outcome stratified by type of cardiac malformation, specific ventricular morphology, type of connection, etc., have been reported giving mid- and long-term follow-up.[4,14–24,26–31,39,82,112,113,127,131–141,143–145,148–154] Various patient groups have been analyzed, including the younger Fontan patient, the adult-Fontan, the patient without pre-Fontan sinus rhythm, etc. Outcomes have been reviewed in those patients staged with a bidirectional Glenn and those who have or have not undergone routine fenestration. Outcomes have been analyzed in the context of specific anatomic risk factors (i.e. pulmonary artery caliber, subaortic stenosis, atrioventricular valve regurgitation, etc.) and by numbers of risk factors. With the Fontan experience extending now > three decades and with ongoing evolution in type of connection, it is not surprising that outcomes, both short-term and longer-term continue to improve. We have discussed earlier in this chapter how specific risk factors can adversely affect outcome and how with the various staging maneuvers and correction of the specific risk factor, outcomes can be enhanced. Amongst a cohort of patients with tricuspid atresia and followed for 25 years, overall survival was 79%.[152] In this Mayo Clinic experience, 79%. operative mortality steadily declined and was 2% (one of 58 patients) during the most recent decade. Late survival also continued to improve. Age at operation had no effect on operative mortality, and late mortality was significantly increased only in patients who were operated on at age 18 years or older. Eighty-nine per cent of surviving patients are currently in New York Heart Association class I or II. When one looks back at the earlier Fontan experience at the Mayo Clinic, Mair and his colleagues reported the mortality for double-inlet ventricle from 1974 through 1980 to be 21%, declining to 9% in the years 1981 through 1989.[77] Gentles and his colleagues from the Boston Children's Hospital had a similar experience as reported in their 1997 publication.[23] Mortality in the first quartile of their large experience was 27.1%, dropping to 7.5% in the most recent quartile. In a multivariate model, the following variables were associated with an increased probability of earlier failure: a mean preoperative pulmonary artery pressure of 19 mm hg or more, younger age at operation, heterotaxy syndrome, mitral atresia, an atriopulmonary connection at the right atrial body or appendage, and absence of a baffle fenestration. The probability of survival in the Fontan state was 84.9% at 1 month, 80.5% at 1 year, 78.5% at 5 years, and 71.4% at 10 years. Their analysis by era showed improved survival in the 1990–91 cohort compared with their earlier experience. Their data also showed poorer long-term survival in patients requiring a pacemaker before the Fontan and in those whose ventricular morphology departed from a single left ventricle with concordant ventriculoarterial connections or with a single right ventricle or ventricle of indeterminate morphology. Obviously the era in which the Fontan was performed influenced outcome. Again, looking at data from the Mayo Clinic, they reported on 352 patients who underwent the Fontan operation before 1985. The overall 1-, 5-, and 10-year survival was 77%, 70%, and 60%, respectively. In this experience a univentricular heart or complex heart malformation other than tri-

cuspid atresia, earlier year at operation, heterotaxia, increased pulmonary artery pressure, atrioventricular valve regurgitation, and worse New York Heart Association class were associated with poorer survival. Stamm and his colleagues reported in 2001 the long-term results of the lateral tunnel Fontan operation performed on 220 patients between 1987 and 1991.[143] The median age at the operation was 3.9 years with a mean follow-up of 10. 2 years. There were 12 early deaths, 7 late deaths, 4 successful takedown operations and 4 heart transplantations. The Kaplan–Meier estimated survival was 93% at 5 years and 91% at 10 years. Freedom from new supraventricular arrhythmias was 96% at 5 years and 91% at 10 years, while freedom from a new bradyarrhythmia was 88% at 5 years and 79% at 10 years. Imai and his colleagues reported in 1997 a 10 year survival after a modified Fontan procedure in the absence of atrioventricular valve regurgitation to be 93%, compared to a survival of 84% of those with atrioventricular valve regurgitation.[123] Bando and his colleagues have reported a 10-year actuarial survival of 93.5%, with overall early and late mortality of 5.4% and 0.8% respectively, of a cohort of 129 patients operated between 1988 and 1998.[139] This group identified Down syndrome as a risk factor for decreased late survival,[139] although certainly a successful Fontan operation can be performed in the patient with this syndrome.[139A] Gates and his colleagues reported a 5% operative mortality in adults undergoing the Fontan procedure, with actuarial survival rates at 3, 6, and 12 years of 95%, 95%, and 81%, respectively.[14] These results are similar to those reported from Toronto.[20] Veldtman and his colleagues reported on 61 adults older than 18 years of age at the time of the Fontan operated on between 1882 and 1998. The median age at operation was 36 years with a median follow-up of 10 years (range 0–21 years). The actuarial survival was 80% at one year, 76% at five years, 72% at 10 years, and 67% at 15 years.[20]

We have reported over the years our Fontan mortality at the Toronto Hospital for Sick Children. Coles and his colleagues reported on our Fontan experience from January 1976 to December 1985.[155] The surgical mortality in these 109 patients was 13.8%, and we identified as risk factors for early and late mortality the diagnosis of univentricular heart, previous pulmonary artery banding, the use of a direct right atrial–pulmonary artery connection in the patient with tricuspid atresia. We had previously reported those morphological features contributing to a poor Fontan outcome, specifically myocardial

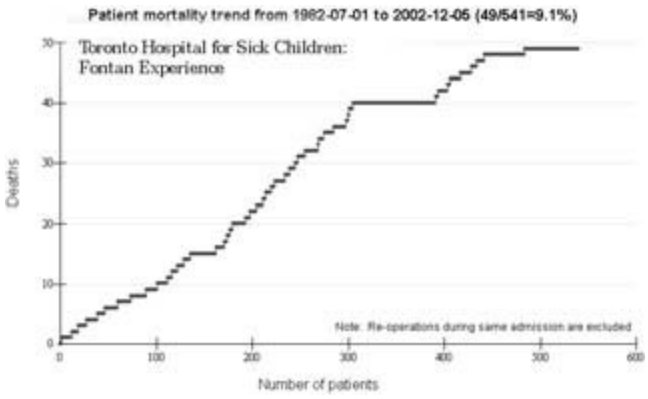

Fig. 36-8 Toronto data showing cumulative summation of patient mortality for Fontan procedure was extended to December 5, 2002. Most of the mortality occurred in the first 300 Fontan operations.

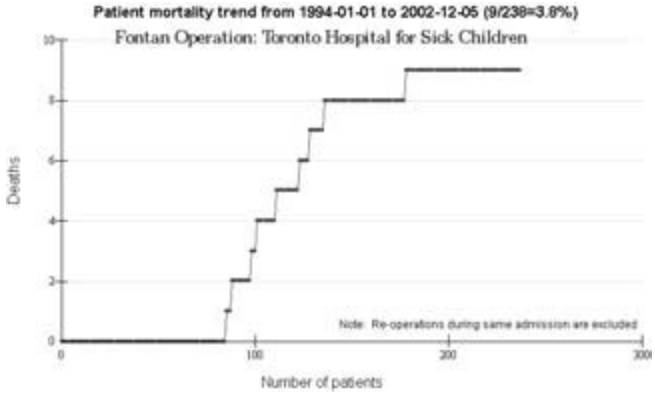

Fig. 36-9 Again the Toronto experience showing dramatic improvement in Fontan mortality.

hypertrophy and previous pulmonary artery banding.[63] We addressed the utility of right ventricular incorporation in the repair of tricuspid atresia, and with this approach from 1976 to 1986, our mortality was 16.1%.[155A] This approach amongst others was abandoned for later more energy efficient connections. In 1991 we reported the results of the Fontan procedure in 306 patients with a univentricular heart operated between 1978 and 1989.[155B] Twenty-five patients died in hospital and 10 died during follow-up. Actuarial survival was 77% at 1 year, 66% at 5 years, and 49% at 10 years. Multivariate analysis identified preoperative poor ventricular function and ventricular hypertrophy as risk factors for death. Our current results show a similar decline in operative mortality as reported by Van Arsdell and his colleagues, from 15% for the first 400 Fontan operations to 4% in the next 100.[147] We attributed this improvement to both staging with cavopulmonary anastomosis and to an extracardiac Fontan, amongst other reasons. In this regard, Azakie and his colleagues of the Toronto Hospital for Sick Children have compared the impact on outcomes of the lateral tunnel vs. the extracardiac Fontan.[144] There was no difference in mortality, but the lateral tunnel group had a higher incidence of postoperative sinoatrial node dysfunction. Results of the Fontan procedure in those with anomalies of systemic and pulmonary venous connections, often those with heterotaxia, continue to improve, with mortality (early and late, nearly 56% a decade ago[41]) to 13%,[156] or lower. Others have also reported improving Fontan results in those patients with heterotaxia.[144A] As we commented earlier whether or not an atrial fenestration currently improves Fontan outcomes is uncertain. Hsu and her colleagues have reported excellent results after the single-stage, non-fenestrated Fontan.[137] So many issues in Fontan surgery "cry out" for randomized trials.[134A,138,139,157,158] One can be reassured, however, that the clinical outcome of fenestrated Fontan patients 10 years after closure is excellent, with improved oxygenation, reduced need for anticongestive medication, and improved somatic growth at latest follow-up.[159] Death (1.3%) or chronic decompensation (3.2%) was rare in this large experience.

While the Fontan–Kreutzer operation has extended and enriched the lives of many patients with complex heart malformations,[23,150,152,160] this operation in any of its forms is in fact only palliation (see Chapter 37). Depending on the type of connection, the presence or absence of fenestration, etc., a number of patients will require ongoing surgical or catheter-based intervention after their Fontan operation (see also Chapter 37). Still,

the evolution from the Glenn to the Fontan–Kreutzer procedure and its modifications has dramatically improved the lives of so many patients with complex heart malformations.[161] The operation has evolved from an atriopulmonary connection with cavo-atrial valves, to total cavopulmonary bypass, lateral tunnel and extracardiac Fontan using pedicled pericardial tunnel vs. conduit reconstruction.[162]

In summary:

- The principle of atriopulmonary connection and atrial separation as introduced by Fontan and Kreutzer and their colleagues is now in its fourth decade of clinical application.
- There continues to be evolution in the surgical construction of the most advantageous Fontan circulation; a circulation that in the absence of forward pulsatile flow is the most energy-efficient. Most centers have evolved away from the classical atriopulmonary anastomosis.
- Early Fontan mortality in well-selected cases is < 5% (Figs 36–8, 36-9).
- The criteria for the performance of a Fontan circulation continue to be examined and refined. Some of the original criteria as outlined by Choussat *et al.*,[9] have been obviated by the evolution to a total cavopulmonary connection and staging procedures (see Chapter 35).
- Outcomes of the Fontan operation are seemingly improved in those with the fewest risk factors.
- There is no such thing as the "perfect" Fontan. Ongoing attrition is a reality in the best of circumstances. At the present time, 10–20 years' survival is often 80% or more.
- Staging with a bidirectional cavopulmonary shunt and correction of anatomic risk factors has likely improved Fontan outcome.
- It is unclear whether aortopulmonary collateral arteries jeopardize Fontan outcome and whether they should be interrupted preoperatively.
- The ideal age for the Fontan operation is unclear. This operation may carry more risk in the adult and in the infant.
- There is ongoing debate as to the value of fenestrating the Fontan circulation.
- The value of post-Fontan lifelong anticoagulation is unclear and if one chooses to anticoagulate, the specific protocol is also unclear.
- Patients surviving Fontan palliation are subject to a wide panorama of complications (see Chapter 37).
- There remains substantial attrition before and exclusion from the Fontan procedure. Strategies must be used to capture more of the "denominator."

Complications of the Fontan Procedure

Most would agree that the Fontan operation is one of the signal achievements in the care of patients with congenital heart disease that took place in the last half of the 20th century.[1] It is entirely appropriate that the designation "Fontan operation" is now firmly entrenched in the vernacular of those who care for children with congenital heart malformations not amenable to a biventricular repair. The benchmark contribution of Fontan and Baudet was published in 1971, having been first performed in 1968 and thus clinical experience with this operation is now in its fourth decade of clinical application.[2] We reviewed in Chapter 36 the evolution in surgical technique, types of heart subjected to Fontan palliation, scrutiny of the original "ten commandments" and evolution in the application of these criteria, as well as those maneuvers that have reduced mortality and morbidity and have enhanced Fontan outcomes.

Suffice it to say, Fontan operative mortality has been reduced to < 5% in most contemporary series, and some report mortality of < 2%[3,4] (see Chapter 36). Such data are of course encouraging, but as we have documented elsewhere many patients who start out on the road of single ventricle palliation either die or are eventually excluded from Fontan palliation.[5–8] Even after a so-called "perfect" Fontan operation, there is ongoing attrition and the need for reintervention.[9] Furthermore, there are a large number of complications that can exact a toll on patients who have undergone the Fontan operation.[10–11A] As shown some years ago by the Mayo Clinic with its very extensive experience with the Fontan operation, both mortality and morbidity can be improved by operating on patients with few if any important risk factors.[11] Indeed, because of the ongoing attrition and reality of late complications, some have questioned the wisdom of "completing" single ventricle palliation with the Fontan operation.[12] The remainder of this chapter will examine in some detail the potential complications of Fontan palliation, and will focus on neurodevelopmental outcome of these patients. Outcomes, early and late, were discussed in the previous chapter.

The list of potential issues is substantial and include:

- right atriomegaly and hepatic dysfunction
- dilatation of the coronary sinus
- freedom from reintervention/reoperation
- thromboembolic events
- protein-losing enteropathy
- pulmonary arteriovenous malformations
- myocardial dysfunction and failure
- ventricular outflow obstruction
- obstruction of pulmonary veins
- recanalization of ligated main pulmonary trunk
- atrial rhythm disturbances
- systemic venous collateralization
- plastic bronchitis
- surgical creation of Wolff–Parkinson–White syndrome
- neurodevelopmental outcome.

Right atriomegaly and hepatic dysfunction

Amongst those patients who underwent a classical type of Fontan operation with a right atrial-to-pulmonary artery connection, a conduit connection between the right atrium and right ventricle, or a Bjork modification, substantial dilatation of the right atrium was inevitable (Fig. 37-1).[10,13–21] This was especially true with the Bjork modification of the Fontan because when the right atrial appendage was anastomosed to the right ventricular infundibulum, there was no atrioventricular valve in the circuit and systolic regurgitation into the right atrium was a certainty.[3] Impressive hepatomegaly was observed with corresponding dilation of the hepatic veins. While we have documented biochemical evidence of hepatic dysfunction, we are not aware of any patient from our institution who progressed to unequivocal cirrhosis related to this complication.[13–15] Others have documented frank liver fibrosis after the Fontan operation or one of its modifications,[14,15] but the incidence of this complication is unclear. With the current tendency towards the lateral tunnel, total cavopulmonary connection or extracardiac Fontan, often with fenestration, it is hoped that this complication should become even less frequent. It is clear, however, that in any patient with a Fontan circulation systemic venous pressure will be higher than normal and thus the sequelae of chronically elevated hepatic venous pressure must be assumed and anticipated.[16,21] Finally, in any patient with ongoing evidence of hepatic dysfunction, postoperative disadvantageous anatomy and hemodynamics must be excluded with a complete hemodynamic and angiographic investigation.[10]

Dilatation of the coronary sinus

In contemporary Fontan surgery, the coronary sinus is positioned in the lower pressure left or pulmonary venous atrium. This results in a small right-to-left shunt.[10,17–21] However, early in our Fontan experience as well as in other centers, the coronary sinus was frequently left to drain into the systemic venous atrium. The substantially higher pressures in the systemic venous atrium had the potential to promote disadvantageous coronary blood flow hemodynamics, perhaps impacting on myocardial perfusion/function, and this could lead to important

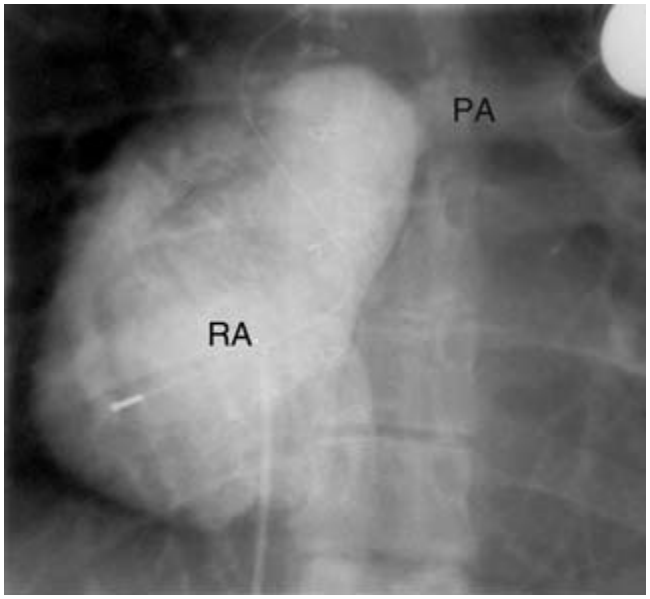

Fig. 37-1 Severe dilatation of the right atrium (RA) after classical Fontan operation. PA = pulmonary artery.

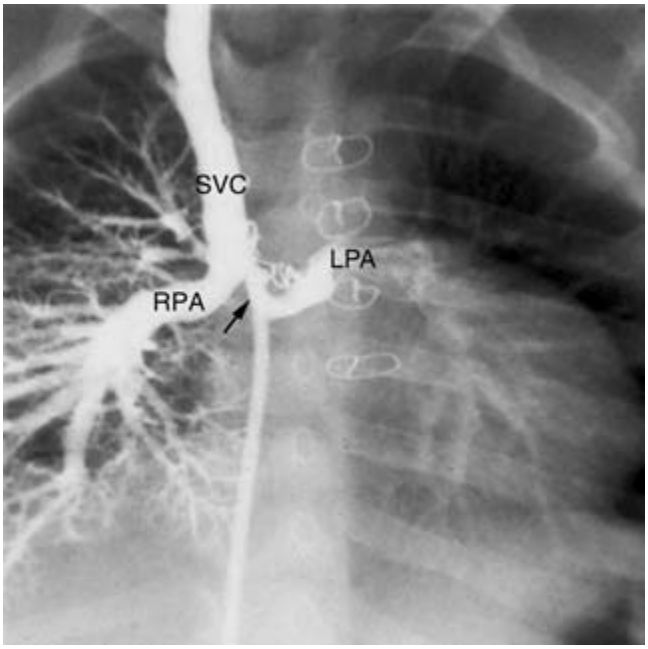
dilatation of the coronary sinus.[17–20] In at least one patient in our series, a very dilated coronary sinus contributed to mitral inflow tract obstruction, and this eventuated in surgical revision.[10,22] In another patient where a left superior caval vein connecting to coronary sinus was not excluded before construction of a Fontan circulation, and with the coronary sinus remaining in the systemic venous circulation, the coronary sinus assumed truly aneurysmal proportions.[10] We have demonstrated reopening of a left superior caval vein connecting to the coronary sinus, and this has been documented both after a bidirectional cavopulmonary shunt and after Fontan surgery as well.

Freedom from reoperation or reintervention

For those institutions routinely fenestrating their Fontan patients, the majority will require some maneuver, usually catheter-based, to close the fenestration.[10] Depending on the initial size of the fenestration, the smaller fenestration often spontaneously closes. But in any large cohort of patients who have undergone Fontan-type surgery, some will require reoperation. Among 334 patients undergoing the Fontan operation at two institutions and followed for a long time, freedom from reoperation for Fontan pathway obstruction was 99% at 1 year after operation and 96%, 86%, and 59%, respectively, at 5, 10, and 15 years after operation.[9] The hazard function for reoperation had an initial very rapidly declining phase and a second phase that was still rising 15 years after operation. Twelve (17%; confidence limits [CL], 13% to 23%) of 69 patients with a right atrial to right ventricular conduit (valved or nonvalved) connection underwent reoperation for pathway obstruction, whereas only 2 (4%; CL, 1% to 10%) of 45 patients with a direct connection to the right ventricle required reoperation. Five (8%; CL, 4% to 13%) of 65 patients with a right atrial to pulmonary artery conduit connection required reoperation for pathway obstruction, and only 2 (1.3%; CL, 0.4% to 3%) of 155 patients with a direct right atrial to pulmonary artery connection required reoperation. We have seen obstruction at the proximal or distal end of an extracardiac Fontan and distal obstruction at a lateral tunnel Fontan (Fig. 37-2).[10] Operations have been required because of conduit obstruction within the Fontan circuit and for residual interatrial communications promoting a substantial right-to-left shunt.[23–26] We have had relatively little experience with conversion from an atriopulmonary connection to either a lateral tunnel or extracardiac



A

Fig. 37-2 Narrowing of the Fontan tract and pulmonary artery. Injections into the superior vena cava (SVC) (**A**) and Fontan tract (**B**) show kink and narrowing of the pulmonary arterial segment between the anastomoses of the superior vena cava and Fontal tract (arrow). The Fontan tract also shows narrowing. A fenestration (f) is seen in the partition between the lateral tunnel and the rest of the right atrium (RA). LPA, left pulmonary artery; RPA, right pulmonary artery.

type of Fontan as has been reported by Kreutzer, Mavroutis and others.[27–31] Some have suggested that adding a bidirectional cavopulmonary connection improves mechanical efficiency in dilated atriopulmonary connections.[32] But clearly patients who underwent a Bjork modification,[32A] any type of Fontan with a right atrial to right ventricular conduit, a direct right atrial-to-pulmonary connection and thus the predisposition to atriomegaly (and rhythm disturbances and thrombosis) may become candidates for reintervention.[10A,B] As discussed later in this chapter, systemic venous collateralization is likely to be an ongoing phenomenon. With some of these patients developing systemic venous to pulmonary vein or pulmonary venous atrium connections, some of these channels will have to be interrupted. The late development of systemic outflow tract obstruction, atrial rhythm disturbances, thrombosis and pulmovention can exact their toll in terms of morbidity and mortality. It is difficult to show a Kaplan–Meier actuarial survival curve(s) that depicts a realistic appreciation for freedom from reoperation/reintervention. In each era, technical modifications may make one operation and its specific complications obsolete, while the new operation has its own intrinsic hazards. Fontan and colleagues found freedom from reoperation in their first 100 patients with tricuspid atresia at 10 years to be about 80%. In Toronto at the Hospital for Sick Children, 86 of our first 569 Fontan patients required reoperation/reintervention, and freedom from reoperation was 88%, 77%, and 54% at 5, 10, and 15 years, respectively.[10] Amodeo and colleagues showed in 1997, a 5-year freedom from reoperation for the extracardiac Fontan of about 85%.[11A]

It is likely that in some patients there will be an ongoing requirement for intervention.

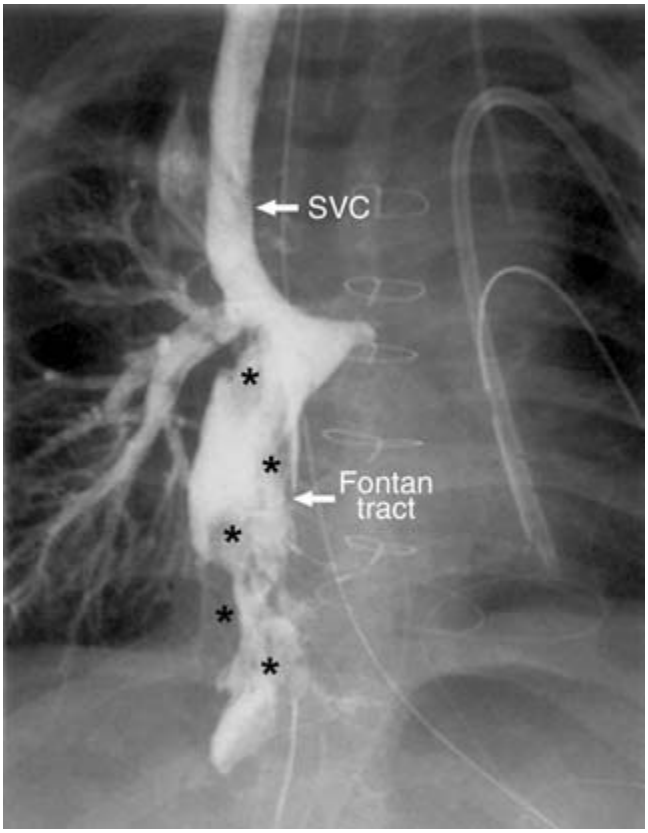

Fig. 37-3 Massive thrombus formation (asterisks) in the Fontan tract and pulmonary arteries. The left pulmonary artery is completely occluded. SVC, superior vena cava.

Thromboembolic events

There is still ongoing discussion and debate as to whether anticoagulation is required for the Fontan patient, and if so, for how long and in what form. Certainly thromboembolic events have been documented to occur acutely after surgical conversion to a Fontan circulation, and late thromboemboli with systemic, including fatal myocardial infarction and pulmonary events have also been substantiated (Fig. 37-3).[33–52] Because of the changing surgical type of connection, presence or absence of a surgically-created fenestration, and various approaches to anticoagulation, both in type and duration, it is difficult to hazard an incidence and to define causality. From a retrospective analysis of 645 patients who underwent the Fontan procedure at the Children's Hospital in Boston between August 1978 and July 1993, 17 patients (2.6%) suffered a stroke after the Fontan procedure.[52,53] The clinical onset of strokes from the time of Fontan operation ranged from 1 day to 32 months (median 40 days). Only 2 patients were receiving prophylactic coumadin therapy at the time of the cerebrovascular accident. The median platelet count in these 17 patients was 274 000/mm^3 ranging from 61 000/mm^3 to 561 000/mm^3. The majority of patients in this series had undergone a lateral tunnel type of connection with the majority fenestrated. Rosenthal and his colleagues from Yale University School of Medicine reviewed the clinical course of 70 patients who underwent this surgery between January 1978 and March 1994.[38] They found that 14 patients (20%) developed a thromboembolic complication during a mean follow-up of 5.2 ± 4.7 years, and the type of surgical connection did not influence the rate of thrombosis. The time from Fontan operation to the thrombotic event averaged 6.1 ± 5.0 years and the overall rate of thromboembolic events was 3.9 per 100 patient years. Thrombus after the Fontan operation has been seen in the right atrium; atrial septum, left atrium and ventricle and is perhaps best appreciated with transesophageal echocardiography. There is some evidence that coagulation abnormalities, both procoagulant and anticoagulant factors, in patients with single ventricle physiology precede the cavopulmonary connection, thus setting the stage for thromboembolic events.[52A] Finally, the study of Varma and colleagues found that 17% of adult patients with the Fontan procedure have clinically silent pulmonary emboli.[33A] The long-term implications of these findings are unclear.

Protein-losing enteropathy

Protein-losing enteropathy is one of the more serious complications of the Fontan procedure and carries with it important morbidity and mortality.[54–72] In the international multicenter study of protein-losing eneteropathy (PLE) after a Fontan procedure, the incidence of PLE in the survivors was 3.7%, although considerably higher in some centers, indeed 25% in one center.[60] The diagnosis of PLE was not just biochemical evidence of protein loss in the stool, but the development of clinical symptomatology related to documented hypoproteinemia caused by gastrointestinal loss. For inclusion into this study, other causes of hypoproteinemia had to be excluded. One-hundred and fourteen patients of 3029 patients undergoing Fontan's procedure or one of its modifications between 1975 and 1995 in 35 participating centers developed clinical evidence

of PLE. For the entire cohort the mean surgical mortality was 13.3% ± 9.5%. There has not been one consistent treatment protocol and any number of therapies have been utilized with varying success. These include dietary manipulation; steroids; heparin; atrial fenestration; takedown to either a bidirectional cavopulmonary anastomosis or to circulation where the pulmonary circulation is dependent on a systemic-to-arterial shunt; or cardiac transplantation. This is a particularly egregious complication with very important morbidity and mortality. In any patient with enteric protein loss, a cardiac catheterization should be carried out to assess post-Fontan hemodynamics and anatomy, but pericardial constriction must be excluded as well. Finally, one must remember the experience recorded by McMahon and colleagues and others who described the appearance and exacerbation of PLE by exposure to high altitude.[73,74] The likely mechanism was an increase in pressures in the pulmonary artery which was then reflected in increased pressures in the venoatrial compartment. Rychik and Gui-Yang have provided evidence that raised superior mesenteric vascular resistance is found in patients with protein-losing enteropathy.[74A] The mortality of protein-losing enteropathy has been suggested to be as high as 50% at 5 years from the time of initial diagnosis.[54,60] Rychik and Spray have recently summarized those strategies to treat protein-losing enteropathy.[62] It is clear from the many studies of PLE, that the patient should undergo a complete postoperative cardiac catheterization with angiography to obtain filling pressures and to exclude any source of mechanical obstruction to systemic venous flow.

Worsening cyanosis following the Fontan procedure

The patient after a successful Fontan procedure is usually acyanotic at rest unless an atrial fenestration has not been closed, thus permitting an obligatory right-to-left shunt. The overwhelming majority of patients with no fenestration at atrial level have a transcutaneous oxygen saturation of at least 94% or higher. If the arterial oxygen saturation is < 90%, then one is obliged to define the etiology of the hypoxemia.[10,75] The following are the more common anatomic causes for hypoxemia following the Fontan operation:

- shunting through a surgically created atrial fenestration
- shunting through a residual interatrial communication
- systemic venous collateralization with connection either to pulmonary venous atrium or to a pulmonary vein
- pulmonary arteriovenous malformations
- unrecognized (pre-Fontan) connection of a hepatic vein with the coronary sinus or left (pulmonary venous atrium) atrium or pulmonary vein
- reopening of a left superior caval vein to the coronary sinus (with coronary sinus draining into the pulmonary venous atrium)
- partially or completely unroofed coronary sinus
- reopening of a levoatrial cardinal vein
- interatrial right-to-left shunting via thebesian veins
- intrinsic pulmonary pathology
- diaphragmatic paresis.

Pulmonary arteriovenous malformations

From the list shown above, one etiology for post-Fontan progressive hypoxemia is the development of pulmonary arteriovenous malformations (Fig. 37-4).[10] This development is very serious and portends clinical deterioration often leading over a protracted period to death. The etiology for the development of pulmonary arteriovenous malformations following the Fontan operation remains uncertain.[10,76–98] Clinical observations suggest that exclusion of the hepatic veins and thus the hepatic venous effluent from the pulmonary circulation may be causal to the development of pulmonary arteriovenous malformations,

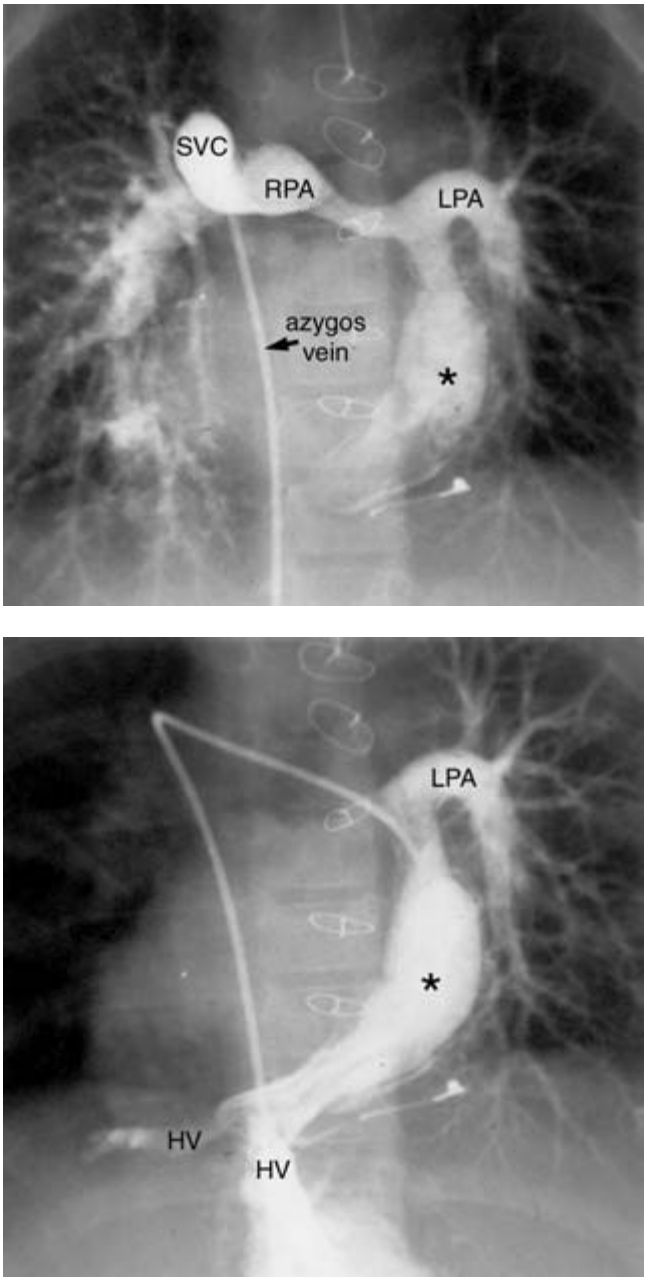

Fig. 37-4 Pulmonary arteriovenous malformation after Kawashima operation. The patient with left isomerism and interruption of the inferior vena cava underwent connection of the right superior vena cava draining the azygos vein to the right pulmonary artery. The patient developed pulmonary arteriovenous malformation. The patient underwent diversion of the hepatic venous flow to the left pulmonary artery (LPA). Injections into the right pulmonary artery (RPA) (**A**) and lateral tunnel (asterisk) (**B**) demonstrate that the right lung shows angiographic features of arteriovenous malformations, while the left lung does not. HV, hepatic vein; SVC, superior vena cava.

and that inclusion of the hepatic venous blood into the pulmonary circuit may reverse their formation.[76–98] This observation was apparently overlooked in one of the earliest reports of pulmonary arteriovenous shunting following Fontan's operation.[85] The similarities to pulmonary arteriovenous shunting in severe liver disease are interesting and their reversal by liver transplantation is provocative.[86–90,99] Indeed, the development of pulmonary arteriovenous malformations has been well documented following the Kawashima operation where the hepatic veins are excluded from the pulmonary circulation[76,77,79,80,81,83,91] and reversed in most after hepatic vein inclusion, a successful maneuver also reported by others.[93–95] Historically, the development of pulmonary arteriovenous malformations following the classical Glenn anastomosis has been very well documented.[100–104] In none of the substantial reviews of this complication that emanated from either Yale or Toronto was hepatic venous exclusion considered as causal.[102–104] Indeed, the Toronto group speculated that maldistribution of flow to the dependent portion of the right lung and lack of pulsatile blood flow were possible etiologies.[102,103] Indeed, in other earlier reviews of the causes of late deterioration after the classic cavopulmonary connection hepatic vein exclusion was not considered causal.[105,106] In one patient in our institution who underwent the Laks modification of the Fontan procedure,[107] with diversion of inferior caval blood to the right lung and superior caval blood to the left lung, pulmonary arteriovenous malformations developed only in the left lung. We have identified a number of patients with left atrial isomerism who developed bilateral pulmonary arteriovenous malformations following the classic Kawashima operation.[10,95] Indeed, while some degree of hypoxemia should be anticipated after the Kawashima operation with oxygen saturations often in the mid-80s, systemic oxygen saturations substantially lower suggest the development of pulmonary arteriovenous malformations.

Duncan and his colleagues have performed a histologic analysis of pulmonary arteriovenous malformations in two children with cyanotic congenital heart disease.[84] Their study did not elucidate the role of the liver in the formation of pulmonary arteriovenous malformations. The histologic correlate of pulmonary arteriovenous malformations seems to be greatly increased numbers of thin-walled vessels, but application of immunohistochemical techniques suggests that the rate of cellular proliferation is not increased. It is unclear whether the histologic and immunohistochemical markers of the pulmonary arteriovenous malformations in these patients with cyanotic congenital heart disease are the same as in patients with the Weber–Osler–Rendu condition. The incidence of the development of pulmonary arteriovenous malformations in patients with cyanotic congenital heart disease is uncertain and their ascertainment is in large part methodology-dependent as shown by Chang and colleagues.[82] The issue of methodology is of paramount importance in establishing the diagnosis of pulmonary arteriovenous malformations. Contrast or bubble-echocardiography is helpful in making this diagnosis. It is important that if this technique is used that contrast or bubbles be injected directly into the pulmonary artery(s). The early appearance of bubbles/contrast in the left or pulmonary venous atrium is very suggestive of this diagnosis. Yet false positives are common if the injection is performed in a peripheral or even a central vein because of potential anatomic connections between systemic veins and the pulmonary veins or left or pulmonary venous atrium as we have discussed earlier in this review and elsewhere.[10] Furthermore, even very small communications between the right atrium or lateral tunnel and the pulmonary venous atrium will contribute to early appearance in the pulmonary venous atrium.[10] The angiographic appearance of diffuse pulmonary arteriovenous malformationss may be diagnostic, but all-too-often this recognition occurs relatively late in the course of the disease (Fig. 37-4).[10] Some years ago we suggested that the incidence of pulmonary arteriovenous malformations following the classic cavopulmonary shunt ranges from about 11% to 21%.[102,103] It will likely escalate with time in those patients with the classic Glenn operation or Kawashima-type operation.[10,95] Other surgical maneuvers have been reported to resolve pulmonary arteriovenous malformations in a patient with a Kawashima operation. Heart transplantation provided for resolution of pulmonary arteriovenous malformations in one patient, and a heart and single-lung transplantation in another.[96,97] Others have modified the cavopulmonary connection so as to include hepatic venous blood in the pulmonary circulation.[92,93] Because pulmonary arteriovenous malformations have been seen in the patient with Weber–Osler–Rendu syndrome and can be seen in other cardiac malformations where hepatic venous blood is conveyed to the lungs, the role of hepatic venous effluent has yet to be fully defined.[97] In this regard, unequal distribution of hepatic venous flow has been attributed to the causality of pulmonary arteriovenous malformations[92,93,94A] and Uemura and colleagues and others have redirected hepatic venous flow to remedy this complication.[92,93] This has usually been achieved by reconstructing the geometry of the intra-atrial tunnel.[92] Another approach to direct or convey hepatic venous blood to the lungs after a Kawashima-type operation is to connect the hepatic veins to the azygos vein as reported by Baskett, Kaneko and their colleagues and others.[92A,B,C] Finally, in some patients with left atrial isomerism, both systemic and pulmonary arteriovenous malformations have been seen,[108,109] although we did not appreciate systemic arteriovenous malformations in the large cohort of patients with left atrial isomerism seen in Toronto.[8]

Myocardial dysfunction and failure

One should not be surprised that all centers performing Fontan surgery have documented ongoing morbidity and mortality following Fontan surgery.[9–11,16,110,111] The reasons for this attrition are clearly multifactorial and complex, but one factor contributing to this attrition is deteriorating ventricular function, both systolic and diastolic. One can postulate many reasons why a patient with a "single" ventricle, either left or right, might have abnormal ventricular function. Firstly, the underlying myocardial substrate might be intrinsically abnormal, as suggested by Sanchez-Quintana *et al*. in their analysis of the myoarchitecture and connective tissue of hearts with tricuspid atresia.[112] Supporting this view, Akiba and Becker also found that the left ventricle was intrinsically abnormal in hearts with pulmonary atresia and intact ventricular septum,[113] indeed perhaps the "Achilles" heel of this disorder. One should expect that myocardium chronically volume-loaded and/or subjected to longstanding hypoxemia would have depressed ventricular function. While the relationship between ventricular diastolic function and compliance is complex, there is ample literature showing that myocardial hypertrophy is a risk factor for the Fontan procedure, and that patients with systemic outflow tract

obstruction and myocardial hypertrophy had both a higher Fontan mortality and in follow-up did less well than those without myocardial hypertrophy.[114–124] Observations from a series of papers published from Toronto some years ago clearly showed that "abnormal" myocardial hypertrophy was a risk factor for poor outcome of Fontan surgery.[116–120,123] In our center, this risk factor has been essentially neutralized with staging with a bidirectional cavopulmonary shunt and either enlargement of the ventricular septal defect or construction of a proximal pulmonary trunk–aortic anastomosis of the Damus–Kaye–Stansel type, an approach advocated by the Mayo Clinic as well which preferred enlargement of the ventricular septal defect.[121]

Contractile or ventricular function has been assessed using a variety of methodologies before and following the Fontan procedure as has regional wall motion.[125–129] Contractile function can be anticipated to recover in some patients with "single" left ventricle after conversion to a Fontan circulation.[129] In the echocardiographic study of Sluysmans and colleagues ventricular volumes in patients with double-inlet left ventricle and tricuspid atresia before the Fontan were two to three times normal.[129] In patients < 10 years of age converted to either a Glenn or Fontan circulation, ventricular dimensions, volumes and wall stress all diminished and left ventricular function and contractility improved after surgery. In those undergoing surgery > 10 years of age, few demonstrated improvement in left ventricular function. Indeed, postoperative ventricular function and contractility were inversely related to age and to aortic saturation measured before surgery. Any number of studies have shown that regional wall motion abnormalities are common in univentricular hearts. Kurotobi and colleagues suggest that such ventricular systolic abnormalities are caused by the rudimentary right ventricle.[130] In their study, the rudimentary right ventricle caused a regional wall abnormality which resulted in asynchronous contraction of the main or dominant ventricular chamber. There are certainly factors other than the rudimentary right ventricle as indicated earlier that may depress or alter regional contractile function including a primary alteration in the arrangement of ventricular fibers, abnormal ventricular conduction, myocardial fibrosis from chronic volume and/or pressure overload, etc. These authors go on to suggest that the rudimentary right ventricle which is usually at systemic pressure affects the regional wall motion in the corresponding area of the dominant ventricle through the direct effects on a second high pressure chamber. We had previously shown considerable variability in size and position of the rudimentary right ventricle, but how these morphologic features translate into such regional wall motion abnormalities, both their presence and severity, is unknown at this time.[131] The role of ventricle–ventricle interaction has been tentatively explored in patients with "single" left ventricle.[132,133] Others have demonstrated changes in right ventricular geometry in patients with the hypoplastic left heart syndrome after the hemi-Fontan procedure,[134] reflecting ventricular unloading and remodeling. Because the native subpulmonary infundibulum in patients with the hypoplastic left heart syndrome is so well expanded, one would not anticipate ventricular outflow tract obstruction after volume unloading surgery. However, **v**entricular volume-unloading surgery including the bidirectional cavopulmonary shunt, the hemi-Fontan, and Fontan and subsequent ventricular remodeling can promote rapid ventricular outflow tract obstruction.[134–136] Furthermore Senzakie and coworkers have shown that Fontan physiology is associated with disadvantageous ventricular power and afterload profiles and has limited ventricular reserve capacity.[134A]

Finally, in the consideration of ventricular form and function after Fontan surgery, a host of other findings have been documented including what has been designated an acute hypertrophic cardiomyopathy as an early response of the systemic ventricle during transition to the Fontan circulation.[137] Penny and his colleagues from the Brompton Hospital in a series of papers showed incoordinate motion of the ventricular wall after the Fontan operations.[138–140] These observations were based on Doppler findings of abnormal systolic atrioventricular inflow and diastolic filling. With deteriorating ventricular function, one might anticipate the development or worsening of atrioventricular valve function.[110,111] The "chicken and egg" phenomenon must of course be taken into consideration, but we have certainly observed worsening tricuspid valve function in the patient with mitral atresia after Fontan surgery, and progressive regurgitation of the common atrioventricular orifice after Fontan surgery, especially in the group of patients with so-called isomerism of the atrial appendages, The prevalence of worsening atrioventricular function after Fontan surgery is uncertain.

Systemic outflow tract obstruction

Systemic outflow tract obstruction has been amply documented to occur in some patients after a Fontan operation.[141] The substrate for systemic outflow tract obstruction is likely present in many of these patients before the Fontan operation, especially those with a discordant ventriculoarterial connection and a history of increased pulmonary blood flow.[116,118–120,142,143] The ventricular septal defect in these patients is frequently marginal in size from the start and thus predisposed to disadvantageous diminution in size.[116,118–120,142,143] There are any number of mechanisms responsible for the development of ventricular outflow tract obstruction after the Fontan operation.[144–147] The ventricular septal defect as characterized by Anderson and his colleagues and others is usually muscular and often smaller than the aortic root, especially in those who required pulmonary artery banding.[116–118,148] Changes in ventricular geometry occurring relatively early after volume unloading surgery as found in the study of Chin and Fogel and their colleagues contribute to functional alterations in the VSD.[128,149] Donofrio and her colleagues have also demonstrated early changes in ventricular septal defect size in the "single" left ventricle after volume unloading surgery.[135] Their observations showed that in the "single" left ventricle, diminution in size of the ventricular septal defect occurs early and is related in part to acute alterations in ventricular geometry accompanying ventricular unloading surgery. Van Son and his colleagues have shown instantaneous subaortic outflow tract obstruction after volume reduction in hearts with a dominant left ventricle, rudimentary right ventricle and discordant ventriculoarterial connections.[136] As we have shown in a series of papers emanating from this institution many of the patients with either pre- or post-Fontan systemic outflow tract obstruction had required banding of the pulmonary trunk ± repair of aortic arch obstruction in the staging towards the Fontan.[116,118–120,142,143] Banding of the pulmonary trunk promotes both myocardial hypertrophy and volume reduction, and thus this maneuver contributes to diminution in size of a VSD predisposed to spontaneous diminution in size. Finta and her colleagues from Ann Arbor reported a series of patients who

developed systemic outflow tract obstruction after the Fontan procedure.[146] They found a 12% incidence of ventricular outflow tract obstruction after the Fontan procedure. This complication was recognized at a median of 28 months after the Fontan operation. Some years ago[144] we identified 12 children from a population of 306 Fontan patients (3.9%) who developed systemic outflow tract obstruction. In our population, this complication was recognized at a median of 2.5 years after the Fontan operation. Because of our long interest in the pathology of systemic outflow tract obstruction in these hearts, we have had a relatively low threshold for enlarging a potentially restrictive ventricular septal defect or performing a Damus–Kaye–Stansel operation before or at the time of the Fontan operation. This could explain the difference in the incidence of this complication between Toronto and Ann Arbor.[147] Because systemic outflow tract obstruction with the resulting myocardial hypertrophy has been identified as a risk factor for the Fontan procedure this complication has largely been neutralized by staging and either construction of a pulmonary–aortic connection or enlargement of the ventricular septal defect.[120,121,123,124,150–157] In some patients developing systemic outflow tract obstruction late after a modified Fontan operation, Suhara and colleagues were able to performa Damus–Kaye–Stansel-type operation reopening the closed pulmonary trunk.[157A] This approach requires a competent or nearly so pulmonary valve.

Obstruction of pulmonary veins after the Fontan

Any impedance to pulmonary artery flow can compromise the functionality of the Fontan circulation. Obstruction to pulmonary venous flow has been observed in some patients after a modified Fontan procedure.[158–164] Fogel and Chin identified 12 cases of pulmonary venous obstruction amongst 297 patients who had undergone 307 Fontan procedures.[158] The mechanisms responsible for the obstruction included narrow pulmonary vein ostia in six patients; narrow left atrial outlet in four; and atrial baffle obstruction in three. Berman and his colleagues reported two patients, both with heterotaxia, in whom late onset pulmonary venous pathway obstruction was recognised, after the Fontan procedure.[161] In one of the two patients, venous orifice obstruction was caused by the intra-atrial baffle and a fibrotic remnant of septum primum. A 5.0 mm diameter common pulmonary venous orifice was further narrowed by the atrial baffle suture line in the second patient. A grossly enlarged right atrium following an atriopulmonary connection has been identified as the etiology for obstruction of the right pulmonary veins in some patients.[159,162–164] Several such reported patients have shown improvement after conversion to a total cavopulmonary connection as documented both by Kreutzer and her colleagues and others.[27–31] We have identified similar mechanisms but have not systematically Dopplered the right pulmonary veins in all of our patients who had undergone a right atrium–pulmonary artery type of Fontan connection. Magnetic resonance imaging has also proven helpful in defining the mechanism of extrinsic pulmonary vein compression between the enlarged atrium and the spine and/or descending aorta.[159,160] It is likely that a mild degree of right pulmonary vein obstruction would not be clinically apparent if there was even modest redistribution of pulmonary blood flow. O'Donnell and colleagues from the Children's Hospital in Boston in 2003 reported 29 patients with pulmonary vein compression from a cohort of 1995 patients undergoing a hemodynamic catheterization between June 1999 and March 2001.[161A] Of these 29, 19 had single-ventricle physiology and 10 had two-ventricle physiology. Six of these patients showed no measurable pressure gradient at catheterization with a mean gradient of 2.4 ± 1.9 mmHg in the remainder. The authors raise the suggestion of endovascular stenting of the compressed pulmonary vein as a possible therapeutic maneuver.

Recanalization of ligated main pulmonary trunk

Of > 600 Fontan procedures performed at the Toronto Hospital for Sick Children we have identified three patients in whom recanalization of a ligated pulmonary trunk promoted a substantial left-to-right shunt. The three patients developed very early after the Fontan surgery a loud systolic ejection murmur and echocardiographic-Doppler interrogation showed patency of the main pulmonary trunk. Two patients underwent surgical division of the main pulmonary trunk. In the third patient, two attempts were made to coil occlude in the catheter laboratory the residual connection. Although these attempts did reduce the amount of shunting, residual patency still caused an important left-to-right shunt and surgical intervention was eventually undertaken to completely interrupt the main pulmonary trunk. This complication should be avoidable by completely dividing the main pulmonary trunk, not ligating it.

Atrial rhythm disturbances

The history of atrial surgery for transposition of the great arteries including the Blalock–Hanlon atrial septectomy and the Senning and Mustard forms of atrial repair is interwoven with atrial dysrhythmias reflecting damage to the sinus node and its artery (see Chapter 25A). One should not be surprised, therefore, about the occurrence of atrial rhythm disturbances after the Fontan procedure.[27–31,110,111,162–180] Indeed, the construction of a bidirectional cavopulmonary shunt or the hemi-Fontan procedure may also precipitate atrial rhythm disturbances,[163] implicit to the surgical variations in carrying out these procedures.

The annual incidence of new dysrhythmias in Fontan patients ranges from 0.4% to 13.9% with a mean of 5.0% per year.[162–180] Gelatt when in Toronto and his colleagues reviewed 270 consecutive patients who had undergone the Fontan procedure between 1982 and 1992.[168] Atrial tachyarrhythmias were seen early postoperatively in 55 patients (20%), preoperative atrial tachyarrhythmias being the only risk factor. Follow-up was achieved for 228 early survivors (97%) at a mean interval of 4.4 years. Twenty late deaths occurred. Late tachyarrhythmias were documented in 29% of patients who had undergone an atriopulmonary connection; 14% of those who received a total cavopulmonary connection; and 18% of those receiving a right ventricular connection. Early postoperative atrial tachyarrhythmias, longer length of follow-up, and atriopulmonary connection were independent risk factors for the presence of late atrial tachyarrhythmias. In an earlier paper Weber addressed predictors of rhythm disturbances and subsequent morbidity in 30 patients after the Fontan procedure.[165] Sixty per cent of the patients in this study had undergone an atriopulmonary connection, but for the entire cohort, atrial abnormalities on the preoperative electrocardiogram predicted those patients who developed rhythm disturbances both immediately and late after Fontan's operation. Balaji and colleagues from the Great

Ormond Street Hospital for Sick Children compared the incidence of atrial arrhythmias in patients who had undergone an atriopulmonary connection with those who had undergone a total cavopulmonary connection.[164] Their data suggested that early arrhythmia appeared to be less after a total cavopulmonary connection than after an atriopulmonary connection. In almost all studies, atrial flutter was associated with increased mortality and morbidity. Fishberger and his colleagues from the Children's Hospital in Boston sought to determine those factors influencing the development of atrial flutter after the Fontan.[174] Multivariate analysis identified age at operation (older rather than younger), longer duration of follow-up, extensive atrial baffling, previous atrial septectomy, and type of atrial repair were all associated with development of atrial flutter after Fontan's operation. Just as with a large cohort patients who have undergone atrial repair of transposition, there is likely to be a decreasing stable sinus rhythm and with increased duration of follow-up, an increased incidence of atrial flutter. Reports of sudden death after the Fontan operation have been reported, but such events are fortunately uncommon, and are presumably on a dysrhythmia basis.[162–180] Ghai and colleagues from the Toronto congenital cardiac center for adults have studied the outcome of late atrial tachyarrhythmias in adults after the Fontan procedure.[180] They found that systemic atrioventricular valvular regurgitation and biatrial enlargement are commonly observed in patients who develop atrial tachyarrhythmias after the Fontan procedure and that these patients are more likely to develop right atrial thrombosis and heart failure.[180]

C

Fig. 37-5 Systemic venous collateral connection to the left atrium. **A.** Injection into the inferior vena cava (IVC) visualizes a large right hepatic vein that gives rise to a collateral channel (asterisks). **B.** Selective injection into the collateral channel shows shunting into the left atrium (LA). **C.** The channel was occluded with coils.

Systemic venous collateralization

Systemic venous collateralization will be for many patients a complication following either palliation with a bidirectional cavopulmonary shunt or a Fontan operation, or both. Considerable data about the development and incidence of systemic venous collateralization after the bidirectional cavopulmonary shunt have been published.[181–190] In some patients, the systemic venous connections are to a systemic vein, while in other patients, the systemic venous collaterals connect either to a pulmonary vein or to the left atrium (Figs 37-5, 37-6). Data from Toronto indicated that systemic venous collaterals are seen in about a third of patients after a bidirectional cavopulmonary anastomosis and are found postoperatively when a significant pressure gradient occurs between the superior vena cava and right atrium.[181] Such collateralization occurred more frequently when bilateral bidirectional cavopulmonary shunts were performed as compared to a unilateral cavopulmonary anastomosis.[191] A similar incidence of collateral formation was reported by McElhinney and his colleagues.[190] In the setting of a bidirectional cavopulmonary anastomosis, systemic venous collateralization can promote systemic hypoxemia by reducing effective pulmonary blood flow and by direct connection to either the left atrium or the pulmonary vein. Such venous collaterals can develop very rapidly, indeed within hours of a bidirectional cavopulmonary shunt.[182,185] Systemic venous collaterals may develop from a wide variety of venous channels. Furthermore, such venous collaterals may be occult and unmasked as we have demonstrated using the technique of balloon occlusion venography.[182] The virtually immediate demonstration of systemic venous collaterals by this technique supports the etiology as dilatation of pre-existing venous channels rather than angiogenesis. Peculiar venous collateralization originating at the level of the diaphragm or below the diaphragm has been observed both following a bidirectional cavopulmonary connection or a Fontan, and again such collateralization may connect to a systemic vein or to a pulmonary vein or to the left atrium, or both.[10,192] The pleuropericardial vein is observed quite frequently in this type of collateralization (see Fig. 35-8B).[10] Reed and his colleagues have described a peculiar intrahepatic venovenous fistula following the modified Fontan procedure.[193] From their data it is unclear whether this really developed after the Fontan operation or was present before the Fontan surgery as virtually identical findings have been observed in patients who have not undergone Fontan surgery.[194,195] A similar case with similar conclusions was published by Schneider and colleagues.[196] These observations have led us and others to study the infradiaphragmatic inferior caval vein with angiography before construction of either a bidirectional cavopulmonary shunt or a Fontan-type of procedure.[10,192,197]

There are perhaps fewer data on the incidence of systemic venous collateralization after the Fontan procedure.[188,189] But the incidence of collateralization after either a bidirectional cavopulmonary shunt or a Fontan procedure is unlikely to be static and we would anticipate an increasing incidence of collateralization with longer time from the time of surgery and with changing hemodynamics. We and others have documented the same spectrum of systemic venous collateralization originating from the superior caval vein and its branches after Fontan surgery as observed after the bidirectional cavopulmonary shunt. In addition to collateralization from the superior compartment, fascinating venous collaterals originating from the inferior caval vein and involving the portal vein have been observed. In addition, most peculiar venous channels originating from the atrial septum and coronary sinus (? thebesian veins) and connecting with the pulmonary venous atrium have been observed and some have been obliterated using a transcatheter-positioned device (Fig. 37-6).[24,181,183,198] Finally, one must exclude peculiar connections of the hepatic vein or veins to the coronary

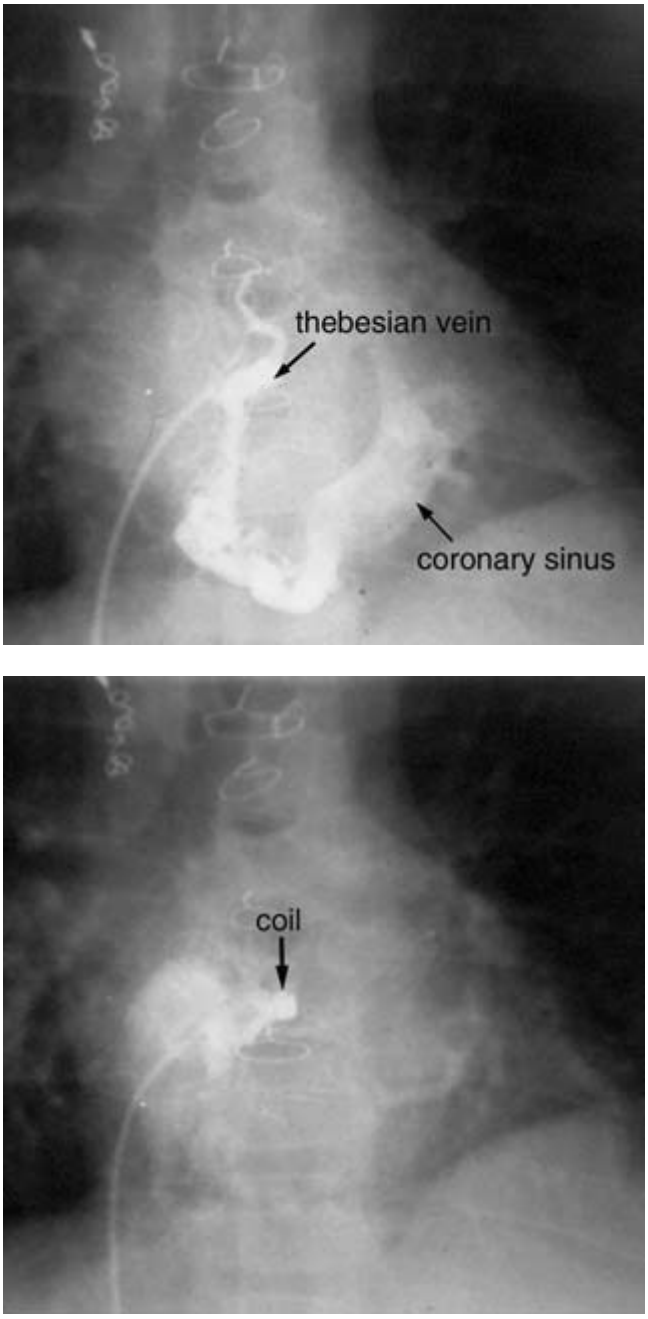

Fig. 37-6 Thebesian vein functioning as a shunting channel of the systemic venous flow into the functional left atrium. **A.** Selective injection into a thebesian venous channel in the Fontan tract shows retrograde filling of the coronary sinus that remained open to the functional left atrium. **B.** The opening in the Fontan tract was occluded with a coil.

sinus or to the left atrium because after conversion to a Fontan circulation, an unrecognised connection may promote a right-to-left shunt.[199–205] Many but not all of these patients with this complication have visceroatrial heterotaxia and one should always define the connection of all of the hepatic veins to the atrial mass as in some patients the hepatic veins may not be advantageously lateralized. With connection of one or an accessory hepatic vein to the lower pressure pulmonary venous atrium, one might anticipate intrahepatic veno-venous steal from the higher to the lower pressure circuit, promoting a progressive right-to-left shunt. Rarely, a congenital communication between the pulmonary vein and hepatic vein will contribute to cyanosis after the Fontan operation.[200] We and others have demonstrated reopening of a left superior vena cava connecting to the coronary sinus after the coronary sinus has been positioned on the low-pressure left atrial side (see Fig. 35–9**)**.[10,185] Similarly, reopening of a levoatrial cardinal vein after Fontan surgery has been shown to be a reason for progressive cyanosis.[10,206] At times it may be difficult to distinguish this congenital venous malformation from an acquired venous collateral.

Plastic bronchitis

Plastic bronchitis is a rare and extremely serious complication of the Fontan procedure, probably occurring in < 1–2% of patients.[207–215] Plastic bronchitis in this setting is characterized by non-inflammatory mucinous casts formed in the trachea and bronchi, producing airway obstruction, and this may result in asphyxiation. This complication has also been rarely observed after a bidirectional cavopulmonary shunt, modified Blalock–Taussig shunt, and the Waterston anastomosis. Languepin and colleagues have suggested that lymphatic leakage into alveolar air spaces may be the mechanism leading to the formation of bronchial casts.[215] This was shown beautifully in the post-mortem study of Hug and colleagues.[214] In their 4 year old patient who died some weeks after a Fontan procedure with elevated central venous pressures, histopathology showed massively dilated pulmonary lymphatics within the lung, and rupture of these lymphatic channels with extravasation into the alveoli. The material in the alveoli was demonstrated to be chyle by lipid staining. Similar findings have been reported by McMahon *et al*.[211] who prefer the designation "Fontan bronchial cast syndrome" to plastic bronchitis. Their patient also had unfavorable post-Fontan hemodynamics related in part to stenoses within the Fontan circuit. Transcatheter stent placement reduced the elevated central venous pressures and transiently reduced the production and expectoration of casts. This youngster seemed improved for about 6 weeks, before once again forming bronchial casts and succumbing with airway obstruction. In one patient seen in Toronto who developed recurrent mucinous bronchial casts requiring multiple bronchoscopies following a Fontan procedure, fenestration of the Fontan circuit did not provide relief, but cardiac transplantation provided prompt resolution of bronchial cast formation. Limited success in the treatment of this serious and life-threatening complication has been achieved using aerosolized urokinase.[210] The etiology of so-called plastic bronchitis or "Fontan bronchial cast syndrome" still remains obscure, but is likely related to unfavorable post-Fontan hemodynamics with elevated central venous pressures and a "fragile" pulmonary lymphatic system.

Surgical creation of Wolff–Parkinson–White syndrome

The appearance of WPW after the Bjork-type of Fontan surgery is consistent with the surgical "creation" of a bypass tract.[179] This finding is very uncommon and limited to those Fontan patients where continuity between right atrium and right ventricle has been achieved by connecting the right atrium directly with the right ventricular infundibulum using a flap of atrial musculature. We have documented this development in only a few patients.

Pancreatitis

Syed and colleagues have reviewed the relevant literature of post-cardiac repair pancreatitis, commenting that this complication is reasonably well described in adult cardiac surgery, but relatively less well studied in the pediatric population.[215B] They cite studies from Finland indicating that children with greater than a 10-fold rise in isoamylase have a higher mortality than those without such a rise. Syed and colleagues report that 4 of 40 patients undergoing a Fontan procedure developed acute pancreatitis after operation, and these patients had evidence for impaired ventricular relaxation.

Neurodevelopmental outcomes

Outcome analysis for any patient who has undergone "repair" of a single ventricle-type malformation must include assessment of neurodevelopmental outcome.[216–223] Uzark and her colleagues have assessed intellectual development in 32 children who have undergone a Fontan repair of complex cardiac malformations from 1986 to 1994.[216] Assessment tools included the Stanford-Binet Intelligence Scale, the Bayley Scales of Infant Development, and the Developmental Test of Visual Motor Integration (VMI). This last tool was used to assess visual spatial and visual motor integration ability. Most children who had undergone the Fontan procedure scored within the normal range for intelligent quotient. The mean score for the VMI was 94.8 with a median score of 93, suggesting a relative mild weakness in visual motor integration. In this relatively small study, no correlation was found between intellectual function or visual motor integration and age at Fontan, pre-Fontan oxygen saturation, or duration of cardiopulmonary bypass. No difference could be found whether the systemic ventricle was of left ventricular or right ventricular morphology. Children who had required deep hypothermic circulatory arrest tended to have lower mean IQ scores than those who had not undergone circulatory arrest. The meaning of these data is uncertain as so many factors including parental socioeconomic and educational status can influence these results. Data for patients surviving first-stage palliation for the hypoplastic left heart syndrome are even more concerning, but in the small series reported by Rogers and colleagues, it is uncertain whether the abnormal neurodevelopmental testing results reflect intrinsic neuroanatomic developmental abnormalities, or the sequelae of surgery, or both.[217] This perspective is important remembering that both acquired and congenital neuropathology have been reported in patients with the hypoplastic left heart syndrome.[218,219] However Kern and colleagues in a small study of children who had undergone at least two of the three palliative

operations for the hypoplastic left heart syndrome found that children with HLHS most often function in the low-normal range of intelligence and adaptive behavior. They go on to suggest that a prolonged circulatory arrest time may result in decreased intellectual function.[220] Forbess and colleagues studied the neurodevelopmental outcome of a recent cohort of patients who underwent the Fontan operation and compared them with a historical cohort of Fontan patients from this institution. This study showed that a staged approach to Fontan earlier in life is not detrimental to neurodevelopmental outcome. While neurodevelopmental outcomes in children after Fontan are in the normal range, their overall performance remains lower than the general population. These results are of course concerning.[223]

In conclusion, the survivor of Fontan palliation is a potential host to a wide variety of complications, including the complications of the arterial switch for those patients with a complex univentricular heart treated with this maneuver including an atriopulmonary connection[224,225] (see also Chapter 25B). Yet we are not persuaded to abandon this approach as Fontan surgery performed in the current era has a lower mortality and morbidity. While we have shown that a cavopulmonary connection may provide equivalent survival,[226] survival is but one aspect of outcome analysis.

Coronary Arteriovenous Fistula

Since the first description by Krause in 1865 of the patient with a coronary arteriovenous fistula,[1] there is now an extensive record of these malformations, with descriptions in young babies and indeed embracing all age-groups including those in their ninth decade of life.[2] Abbott described in 1906 the pathology of some of these lesions.[3] Some 40 years later, Bjork and Crafoord were likely the first to report the surgical treatment of a coronary arteriovenous fistula.[4] Fagan and his colleagues[5] suggest that Haller and Little were the first to report the use of preoperative angiography to diagnose coronary artery fistula.[6]

The site and size of the fistulous communication likely determines in large part the clinical and hemodynamic consequences.[7–20] A wide range of potential complications have been attributed to coronary arteriovenous fistulae including cardiac failure, bacterial endocarditis, coronary and myocardial insufficiency and calcification, dissection and rupture of a dilated vessel.[5,7–12,14,17–34] Fortunately clinically important coronary arteriovenous fistulae are uncommon in childhood,[5,7–10,12–14,17,19,35] but these have been recognized with increasing frequency especially in the adult since the introduction of selective coronary arteriography in the latter half of the 20th century. Their recognition has been enhanced as well by cross-sectional echocardiographic and color flow mapping and magnetic resonance imaging.[36–47] The malformations of the coronary arteries characterized by anomalies of connection or termination can be viewed as those with cardiac or extra-cardiac communications. This chapter will deal with coronary–cameral or arteriovenous fistula with the coronary artery(s) having a normal proximal aortic origin and distal cardiac or extra-cardiac connections (Figs 38-1, 38-2).[5,7–10,46–50] The anomalous origin of the right, left (anterior descending or circumflex), or both coronary arteries originating from the pulmonary trunk are considered separately in Chapter 12.

Incidence

The incidence of coronary arteriovenous fistulae is difficult to ascertain. Increasingly, small fistulae are being detected due to the frequency of coronary angiography in patients with atherosclerotic disease, valvular heart disease or other lesions[11] and owing to the advances in echocardiographic and magnetic resonance imaging.[37,39]

The New England Regional Infant Cardiac Program did not identify any infant with a primary coronary arteriovenous fistula, suggesting how uncommon this condition is.[51] Certainly since this survey was completed before the routine application of cross-sectional echocardiography it is likely that the true incidence was under-appreciated. Interestingly, however, the prospective Bohemia Survival Study also does not mention the birth prevalence of coronary arteriovenous fistulae.[52] Based on some clinical studies, Vlodaver and his colleagues in 1975 suggest a population incidence of 1 in 50 000 for coronary arteriovenous fistula.[48] There is not an obvious gender bias. Kallfelz summarizes some of the literature indicating that coronary arteriovenous fistulae or coronary–cameral anomalies constitute about 0.2% to 0.4% of all congenital cardiac anomalies.[53] He suggests as well that these have been identified in 0.08% to 0.18% of routine coronary arteriograms in adults, constituting 8–13% of the congenital coronary artery anomalies observed in these studies.[53] Yamanaka and Hobbs found 163 instances of small coronary arteriovenous fistulae in 126 595 patients (0.13%) who underwent cardiac catheterization at the Cleveland Clinic.[54] In 62 patients there were multiple or large-sized fistulae (0.05%).

Ventriculocoronary connections are well described in patients with pulmonary atresia and intact ventricular septum (see Chapter 34) and some forms of hypoplastic left heart syndrome (see Chapter 35). Other less common situations where ventriculocoronary connections are conspicuous including aortic atresia with transposition and intact ventricular septum [55] or double-outlet left ventricle and intact ventricular septum have been dealt with elsewhere.[55–59] Coronary–cameral fistulae may complicate other forms of congenital heart disease, including transposition of the great arteries, tetralogy of Fallot, ventricular septal defect, patent arterial duct, etc.[60–69] Acquired fistulae are reported increasingly following trauma,[70,71] coronary or valve surgery,[11] and cardiac transplantation, the latter a sequela of right ventricular endomyocardial biopsy.[72,73] We have observed a small coronary arteriovenous fistula following a right ventricular infundibular incision as well. An interesting case reported by Rozenman *et al*. of a fistula developing in association with progression of atherosclerosis coronary artery disease, raises the possibility that not all 'incidental' fistulae in this group of patients are 'congenital'.[74]

Definition

In this chapter we will consider those conditions where both coronary arteries have a normal origin from the aorta, but one or more branches of the coronary artery connects directly with one of the four cardiac chambers, coronary sinus, coronary vein, superior vena cava, or pulmonary trunk (Figs 38-1, 38-2).[5,7–10,12,46–49] Small interconnections between the coronary vascular bed and bronchial arteries have been amply described,

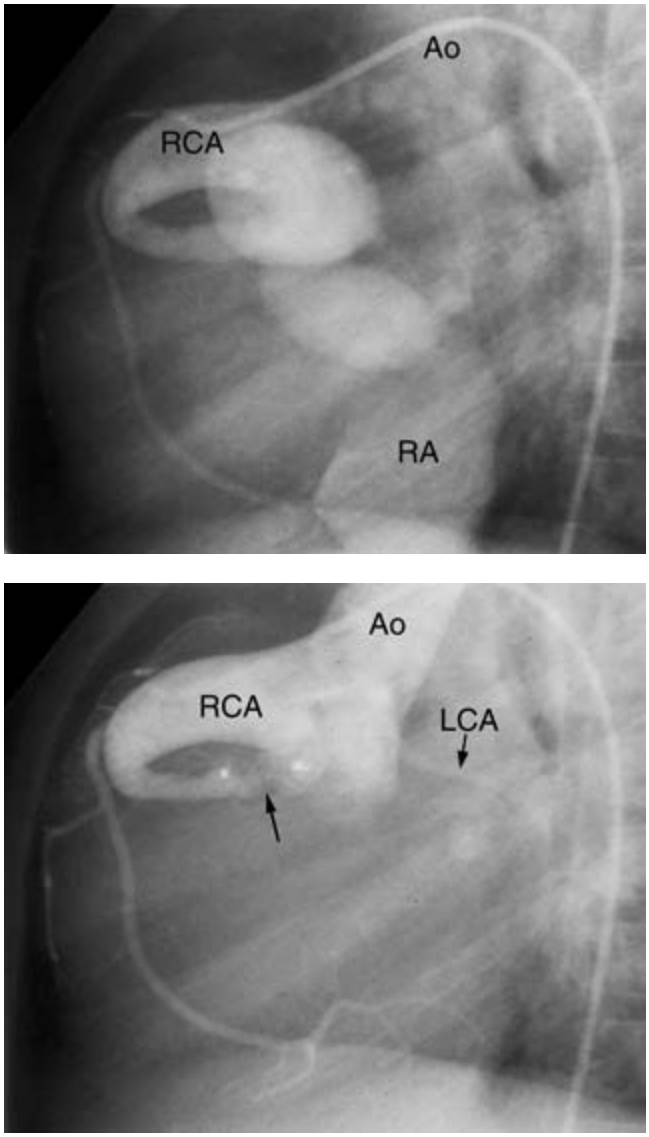

Fig. 38-1 Coronary artery-to-right atrial fistula. **A**. Right coronary arteriogram demonstrates a large fistulous connection of the proximal part of the right coronary artery (RCA) to the right atrium (RA). **B**. Aortogram obtained after deployment of an Amplatzer device (arrow) demonstrates successful occlusion of the fistula. Ao, aorta.

are likely normal and will not be dealt with further in this chapter.[60,61] Rarely a large connection between coronary artery and bronchial artery will result in a coronary artery steal.[24] Coronary arteriovenous fistulae should not be considered pathologic curiosities. They predispose to myocardial ischemia, bacterial endocarditis, at times substantial left-to-right shunts when connected to right heart chambers and congestive heart failure.[5,7–12,14,17–34] When connected to the left heart chambers, they "behave" like aortic regurgitation, depending on their size.[5,7–12,14,15,17–23,39,44,46–49,62,63] Occasionally a coronary arteriovenous fistula will become aneurysmal, dissect and then may rupture with resulting pericardial tamponade.[4,5,7–14,17–20,27,29,32,33,40,44,45,64]

Angelini differentiates coronary–cameral fistulae (those having a direct connection with a cardiac cavity) from arteriovenous fistulae (those having connections between arterial and venous plexii, the latter usually draining to the coronary sinus given that this is the usual drainage of most of the cardiac veins).[49] Other authors[7] include both groups as "coronary arteriovenous fistulae," presumably due to the similar clinical presentations and owing to the difficulty at times in demonstrating the venous segment of "arteriovenous fistula" angiographically, as well as pathologically: the presence of arterial flow in veins may lead to intimal hyperplasia and medial hypertrophy.[50]

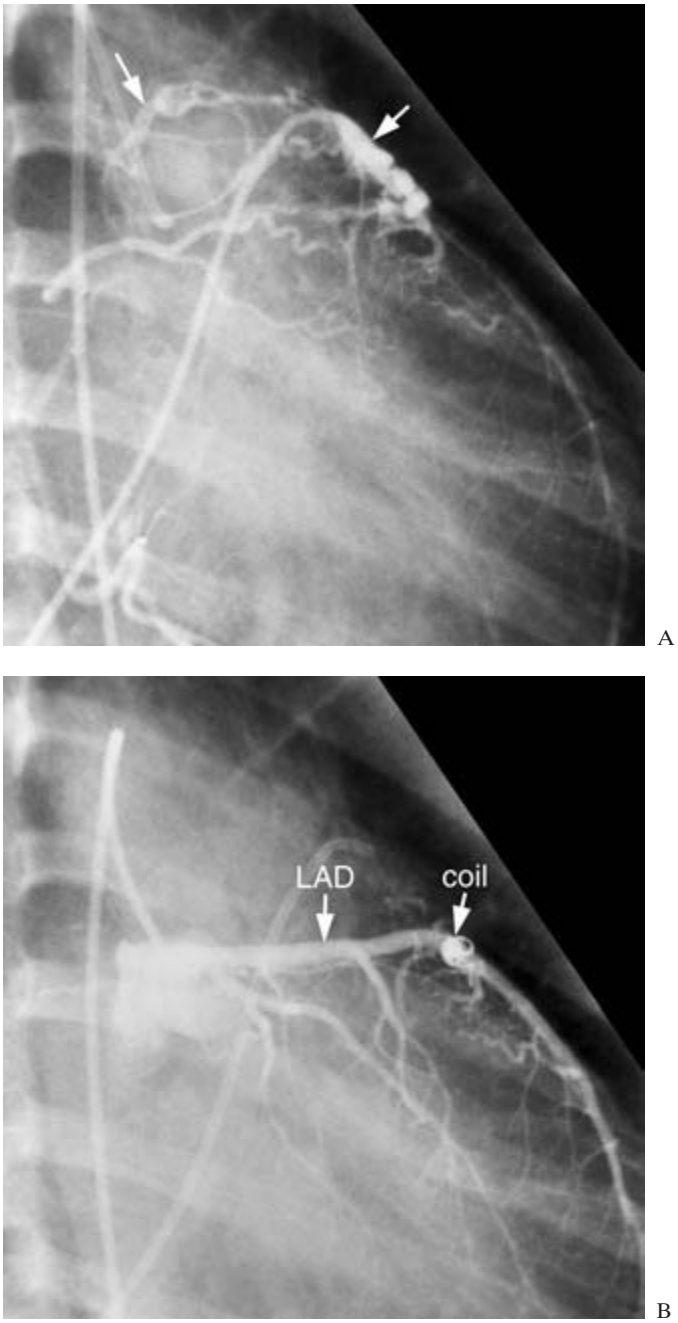

Fig. 38-2 Coronary artery-to-pulmonary artery fistula. **A**. Injection into the pulmonary arterial side of the fistula shows opacification of tortuous coronary arterial branches (arrows). **B**. Left coronary arteriogram obtained after coil embolization of the main fistulous tract shows only minimal shunting. LAD, left anterior descending coronary artery.

Neufeld and Schneeweiss have pointed out that technically, those connections between coronary arteries and left-sided chambers do not represent "arteriovenous fistula" but rather, arterial–arterial fistulae.[8] Despite this, the accepted practice in the literature of including all of these coronary connections to cardiac structures as "AV fistulae", will be followed. Those patients having a direct connection between aorta and a ventricular cavity (aortocameral communications) are discussed in Chapter 15A. We acknowledge the recent embryological thinking that these malformations represent direct communications between the proximal aspects of coronary arteries and persisting sinusoids, would argue for their inclusion in a discussion of coronary arteriovenous fistulae.

Site(s) of origin and termination

The fistulae originate from the right coronary artery in 50–60% of patients, from the left coronary artery in 30–40% and from multiple sites in 2–5%.[5,7,10–12,48,49,62,64–66] More than 90% of the fistulae connect to the right side of the heart, with the right ventricle being most frequent recipient, followed by the right atrium and pulmonary trunk. Connections to the left atrium and left ventricle are considerably less common, accounting for < 10% of the cases. The connections to a cardiac cavity or to coronary veins/sinus may be single, small, insignificant tracts,[10,11] single large or multiple large fistulae,[10,11,50,65] multiple small tracts,[20,21] or racemose angiomas.[22] Fagan and his colleagues also catalogue the types of fistulous connections into four types: (1) simple fistula to a chamber with a side or end connection; (2) multiple connection sites; (3) plexiform or telangiectatic connections (usually to the left ventricle or pulmonary trunk); (4) side-to-side (Fig. 42-2).[5]

Fagan and his colleagues have summarized the features of coronary fistulae in pediatric patients. These are probably the same issues for the adult population with coronary arteriovenous fistulae superimposed on the developing adult matrix of arteriosclerotic heart disease.[5]

Connections to a cardiac cavity or to coronary veins/coronary sinus may be single, small, insignificant tracts,[10,11] single large or multiple large fistulae,[10,11,50,65] multiple small tracts[20,21] or racemose angiomas.[22] The incidence of coronary arteriovenous fistulae is difficult to ascertain. Increasingly, small fistulae are being detected due to the frequency of coronary angiography in patients with atherosclerotic disease, valvular heart disease or other lesions[11] and owing to the advances in echocardiographic and magnetic resonance imaging.[37,39] The right coronary artery gives origin to the fistula slightly more commonly than the left but > 90% of the connections are to the right side of the heart.[5,7,65,10–12] Fistulae involving both coronary arteries occur in 4–5% of patients.[5,7,48,49,62,64,66]

Kirklin and Barratt-Boyes[7] note that the fistulae almost always are part of the normally distributed coronary artery, and may involve either the main vessel or a branch. The involved segment is usually dilated and elongated and may be serpiginous, usually reflecting the size of the shunt. The dilatation may be uniform or focal to a point of being aneurysmal. Associated congenital heart defects have been reported sporadically, including patent arterial duct, complete transposition, tetralogy of Fallot.[67–69] Acquired fistulae are reported increasingly following trauma,[70,71] coronary or valve surgery,[11] and cardiac transplantation, the latter a sequela of right ventricular endomyocardial biopsy.[72,73] We have observed a small coronary arteriovenous fistula following a right ventricular infundibular incision as well. An interesting case reported by Rozenman of a fistula developing in association with progression of atherosclerosis coronary artery disease, raises the possibility that not all "incidental" fistulae in this group of patients are "congenital.[74]"

Noninvasive imaging is now being used to map fistulae.[36–43,45] Until recently, the mainstay of diagnosis was angiography (Figs 42-1, 42-2). This was first reported in the diagnosis of coronary arteriovenous fistula in 1959.[46,47,81] Aortic root injection or selective coronary angiography will show the coronary artery which may be focally or generally dilated, with opacification of the draining chamber or vessel. Branches beyond the fistula may be small and poorly filled due to the myocardial steal. The malformation may be erroneously diagnosed, if, during selective coronary angiography, the catheter tip becomes wedged because of a small vessel, large catheter, or arterial spasm. In this situation, contrast will rapidly appear in veins or cardiac chambers, mimicking shunting. The differential diagnosis of coronary–cameral fistulae from aorto-cameral tunnels is clearly of clinical importance.[82] The clinical recognition of these peculiar communications is discussed in detail in Chapter 15A. The differentiation from acquired fistulous communications has also been discussed.[83] Coronary arteriovenous fistulae may be mimicked by two other abnormalities, the vascularization of cardiac tumours and organized thrombus.[84–89]

Outcome analysis

There is little if any literature documenting fetal recognition and outcome of coronary arteriovenous fistula. As with cardiac tumors (see Chapter 44), the clinical recognition of coronary arteriovenous fistulae has been heightened by noninvasive imaging modalities and thus there is increasing recognition of apparently clinically silent coronary arteriovenous fistula. The clinical findings have been reviewed elsewhere.[7,10] Suffice it to say, symptoms may be apparent in the neonate and young infant, but this is uncommon. Indeed as Liberthson and his colleagues pointed out some years ago, 80% of patients < 20 years of age with coronary arteriovenous fistula are asymptomatic, with only about 20% having symptoms related to the coronary arteriovenous fistula itself.[10] In some patients symptoms reflect the coronary arteriovenous fistula-related complications including congestive heart failure, bacterial endocarditis, or sudden death.[12] In the era of surgical ligation, complications related to surgical interruption in the young patient were quite uncommon, but were more common in the older patient.[10]

Hudspeth *et al.* pointed out the association with a myocardial "steal", especially in the adult with underlying arteriosclerotic vascular disease.[75] While progressive dilatation within the fistula is well recognized, rupture with cardiac tamponade is rare.[4,5,7–14,17–20,27,29,32,33,40,44,45,64] Spontaneous closure of a coronary–cameral fistula has been documented.[76–80] Coronary arteriovenous fistulae may clinically mimic the patent arterial duct, aortopulmonary window, ventricular septal defect with aortic regurgitation, or an arteriovenous malformation of the chest wall or lung. While these fistulae occur in early life, few result in symptoms until the second decade. The incidence of congestive heart failure from long-standing left ventricular volume overload increases with age,[23] as does myocardial ischemia and angina (from the "steal" effect).[24] The latter may

potentiate associated coronary artery obstructive lesions in the adult population.

As indicated above, symptoms from fistulae increase with age.[10] Additionally, older patients have a higher morbidity and mortality associated with the traditional management of fistula ligation.[7,10] These data support a role for elective and early intervention. Thus most investigators advocate closure (surgically or more recently by catheter methods) of hemodynamically significant communications, even in the absence of symptoms. The risks of surgical therapies are low[7] although operative deaths have been reported,[23] as had post-surgical myocardial infarction.[90] Recurrence rates after surgical intervention are not known. Embolization of large fistulae has been reported, either using coils[91–99] or detachable balloons, and other devices (Figs 38–1, 38-2).[100–105] When a fistula is large, visualization of normal distal coronary branches may be difficult due to the rapid run off toward the fistula. It is essential that visualization be complete and the embolization occur distal to all normal branches. Additional proximal fistulous communications may become apparent after the distal lesion is embolized, and underscore the need for careful post-implantation angiography.

A number of technical considerations highlight the potential difficulties involved in occluding high flow lesions within the coronary circulation. While detachable balloons allow precise implantation localization, large guiding catheters are required and early balloon deflation and inadvertent embolization may occur. When coils are utilized, it is critical that the delivery catheter tip is positioned at the point where the coil is desired. With torturous vessels and distal occlusion requirements, standard catheters may be difficult to place and microcoils or detachable coils may be required that are better suited to these specialized situations. With large, high flow lesions, placement of multiple coils may be required. It is important therefore, to select an embolization technique which is suitable for the size and location of the fistula to be occluded.

Connections to extracardiac structures

Connections between coronary arteries and extracardiac structures include connections to pulmonary arteries, pericardial, bronchial and mediastinal arteries and to the superior vena cava. Connections to pulmonary arteries are, like coronary fistulae to cardiac structures, increasingly recognized as an increasing number of patients have cardiac imaging (Fig. 38-2).[5,11,40,65,106–108] They typically extend from proximal left or right coronary arteries to mediastinal or hilar pulmonary arteries and may be single or multiple. While they are often incidental findings, they certainly may be large, tortuous communications of functional significance. Connections between coronary arteries and extracardiac veins are rare, but usually are to the superior caval vein.[5,7–12,14,46–49,66,102] Imaging by echocardiography is possible but the mainstay remains angiography, particularly selective coronary studies. The differential diagnosis includes acquired fistulae, either vascularized adhesions following cardiac surgery, or indirect collateral formation such as in patients with cystic fibrosis. Surgical approaches to management have both been reported, with increasing emphasis on catheter-based therapy.[5–7,10,12–19,24,90–105,109–114] Cheung and his colleagues have shown that after surgical intervention, the native coronary artery either remained dilated and tortuous, or more frequently demonstrated thrombosis with a short proximal stump.[114] Of the 41 patients included in this report, four patients demonstrated recurrence of the fistula.[114] The Pediatric Cardiac Care Consortium reported the outcomes for 35 patients undergoing 37 operations for a coronary arteriovenous fistula between 1984 and 1995.[115] During this time period 27 678 patients were operated on by members of the consortium. Infants under 1 year of age accounted for 12 (35%) of the patients. In this series all but one fistula drained to the right side of the heart. There were no operative deaths, but 2 patients required reoperation for recurrence.[115] The general experience of transcatheter closure has been good, with only a small percentage of patients demonstrating early trivial residual shunting.[116–118]

The clinically silent coronary arteriovenous fistula

One of the more important issues is the prognostic significance and management issues of the clinically silent coronary arteriovenous fistula.[80,106] Some of the considerations in these patients are similar to those patients recognized only by color flow mapping to have a small, clinically silent arterial duct (see Chapter 9). Sherwood and her colleagues have reported the clinical, echocardiographic, electrocardiographic, angiographic findings, and documented follow-up of 31 patients with an echocardiographic finding of a clinically silent coronary arteriovenous fistula.[80] The mean age at diagnosis was 7.2 ± 8.4 years. The indications for echocardiography were heart murmur in 23, congenital heart disease in 2, cardiomegaly in 2, chest pain, stridor, syncope and chest trauma in 1 each. Interestingly in this series of 31 patients, the origin of the fistula was from the left coronary artery system in 27, the right coronary artery in 3, and bilateral in 1.[80] At least one other report of asymptomatic coronary arteriovenous fistulae found a greater incidence of fistula origin from the left coronary artery system.[80] The sites of termination were the pulmonary trunk in 18, right ventricle in 8, right atrium in 2 and left ventricle in 3. Global and regional left ventricular function were normal in all patients at presentation and at follow-up. Stress-dobutamine studies were not performed in these patients. Complete spontaneous closure of the fistula was documented in 7 patients (23%) at a mean follow-up of 2.6 ± 2.0 years. All the other patients remained free of adverse clinical events and free from clinical myocardial ischemia. Thus these authors advocated conservative management with continued surveillance.[80] These authors specifically mention that in these patients with clinically silent coronary arteriovenous fistulae, the life-long risk of complications including aneurysm formation, rupture, dissection, accelerated atherosclerosis, and thromboembolism is unknown. As pointed out in this study and others, spontaneous closure of a coronary arteriovenous fistula is a well-documented phenomenon,[76–79] and Liberthson and his colleagues estimate the rate of spontaneous closure of the coronary arteriovenous fistula to be 1–2%.[10]

Despite a substantial literature devoted to the diagnosis and potential therapeutic strategies for patients with coronary arteriovenous fistula, controversy remains about the indications for and timing of intervention. There is perhaps less discussion when the fistula is large, when symptoms are present, or when there are findings of myocardial ischemia. Many authors advocate interruption of the fistula at the time of diagnosis even in the asymptomatic patient with a small left-to-right shunt, hoping to prevent later adverse events.[7,10,12]

Robert M. Freedom

Cardiac Diverticulum and Aneurysm

Cardiac aneurysms and diverticulum are uncommon in the pediatric population, and while most are congenital in origin, some certainly have their basis in a post-inflammatory or ischemic sequela. There is now some literature documenting fetal recognition of these malformations as well.[1–9]

Cardiac diverticulum have been observed originating in the right atrium;[10–23] coronary sinus;[10,23–37] right ventricle;[10,38–56] left atrium,[10,57–83] left ventricle[10,84–129] and atrioventricular septum or valve[125,126] (Fig. 39-1). Again, none of these diverticula are particularly common, and those found in the right atria and right ventricle are considered rare. Some cardiac diverticula have been found as an incidental finding for investigation of other cardiovascular abnormalities, while in others investigation of atrial or ventricular dysrhythmias led to the recognition of the diverticulum. An abnormal cardiac silhouette on a chest radiograph has also led to the recognition of cardiac diverticulum, especially the large aneurysm of the left atrium or its appendage. The aneurysm of the atrial septum and ductal diverticulum are considered elsewhere (see Chapters 4 and 9). The so-called aneurysm of the membranous ventricular septum is not really an aneurysm, but rather tricuspid valve tissue adhering to the margins of the ventricular septal defect (see Chapters 3 and 26A). Aneurysms and rupture of the sinus of Valsalva are also considered in a separate chapter (see Chapter 15B).

In the consideration of cardiac ventricular diverticulum, some have designated these malformations as diverticula, while others have used the designation, aneurysms. There is certainly not a consensus when designating these conditions. Some have used the term diverticulum when it is associated with other congenital intracardiac and midline thoracoabdominal defects and when the connection to the ventricular cavity is narrow. Others have used the designation aneurysm when it resembles an acquired aneurysm with a wide connection to the ventricular cavity and absence of midline thoracoabdominal defects. This differentiation is not satisfactory because as Hamaoka and colleagues point out the designation diverticulum has been used in the absence of midline defects, and in other reports, the terms aneurysm and diverticulum have been used interchangeably.[54] Others have tried to use the morphology of the condition as the basis for designation. When the wall of the defect contains all three cardiac layers, endocardium, myocardium, and pericardium, and contracts normally or synchronously with the left ventricle, it has been called a ventricular diverticulum. It has been designated an aneurysm when it consists of a fibrous saccular wall, contracts paradoxically, and has a wide communication with the ventricle. But is the aneurysm an acquired or congenital condition? Mardini summarizing those issues about terminology, suggested that the designation of aneurysm has both acquired and congenital implications.[92] An aneurysm may be acquired when it results from trauma, infection, ischemia, postoperative coronary disease, etc. He goes on to suggest that a congenital left ventricular aneurysm may have its etiology in an anomalous left coronary artery originating from the pulmonary trunk. While the coronary lesion is certainly congenital, the left ventricular aneurysm has its origin in an ischemic myocardium. Thus in this instance both causality and terminology have overlapping features.

Right atrial diverticulum or aneurysms

Presumably congenital diverticulum or aneurysms originating from the right atrium are uncommon.[10–23] Varghese and his colleagues and subsequently others have described patients with multiple saccular aneurysms originating from the free wall of the right atrium and the atrial appendage.[11] In the patients described, atrial dysrhythmias have been causally linked to the atrial aneurysms, and these have been successfully treated in some patients by resection of the aneurysms. A congenital diverticulum of the right atrium situated on the floor of the coronary sinus was reported by Petit and colleagues in 1988.[35] In their report of a 50-year-old man with multiple diverticula of the right atrium, Morishita and colleagues suggest that there has been some difficulty in differentiating between a diverticulum and idiopathic enlargement of the right atrium.[14,17,18] Okita and colleagues report a 3-year-old boy with multiple congenital aneurysms of both right and left atria.[12] This child was known to have fetal supraventricular tachycardia, and recurrent rhythm disturbances which led to echocardiography and angiocardiography where the aneurysms were recognized. They were resected with resolution of the rhythm disturbance; histopathology revealed they were composed of fibrous tissue, attenuated myocardial fibers with an endothelial lining. Surgical excision has been recommended to eliminate a potential source of emboli and for treatment of supraventricular arrhythmia.[11–14,18] We are not aware of spontaneous rupture of a congenital aneurysm or diverticulum of the right atrium.

Diverticulum of the coronary sinus

Diverticulum of the coronary sinus has been recognized with increasing frequency since catheterization of the coronary sinus became routine in invasive electrophysiological procedures.[10,23–37] Imaging of the coronary sinus on the levophase of selective coronary arteriography has also led to an increased

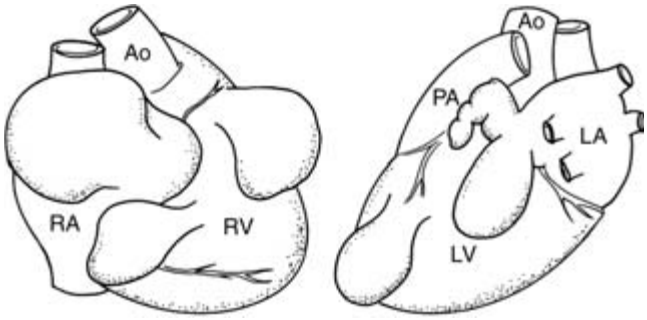

Fig. 39-1 Various cardiac diverticula. A composite drawing shows diverticula arising from the right atrium (RA), right ventricle (RV), left atrium (LA) and left ventricle (LV). Ao, aorta; PA, pulmonary artery.

awareness of abnormalities of coronary sinus shape and position, and thus has led to increased focus on variations in coronary sinus anatomy from the pathologist's perspective.[37] McGiffen and Guiraudon and their respective colleagues amongst others have noted the association between diverticulum of the coronary sinus and the Wolff–Parkinson–White syndrome.[23–32] This association is not always present as in the report of Hamano and colleagues.[36] The coronary sinus diverticulum reported by Di Segni and colleagues was diagnosed by echocardiography in a 2-day-old baby with a hypoplastic left heart syndrome.[33] Occasionally, more than one coronary sinus diverticulum may be present.[31] An enlarging diverticulum of the coronary sinus has been observed, and for this reason the "neck" of the diverticulum was oversewn.[36]

Right ventricular diverticulum

In the consideration of ventricular diverticulum or aneurysm, the occurrence is far less common in the right ventricle than in the left ventricle.[10,38–56] Bharati and her colleagues discussing a 2-month-old infant with a muscular diverticulum of the right ventricle states that there are two types of right ventricular diverticula, muscular and fibrous.[38] A diverticulum of the right ventricle may originate from the apex or from the anterosuperior wall. Hofbeck and his colleagues described three patients with diverticulum of the right ventricle associated with a perimembranous ventricular septal defect.[47,50] The diverticulum in these three patients arose from the anterosuperior aspect of the right ventricle at the junction of the inflow and infundibular portions of the right ventricle and in all three patients the diverticulum behaved like an accessory ventricular chamber, contracting synchronously with the ventricular myocardium, consistent as well with a muscular origin. A divided right ventricle was found in 1 of Hofbeck's 3 patients. In the review from the literature of patients with a right ventricular diverticulum conducted by Hofbeck, 5 of the 22 patients had no associated cardiac anomalies. Amongst those congenital heart malformations encountered in this review were tetralogy of Fallot, double-outlet right ventricle, atrioventricular septal defect, and tricuspid atresia.[38,40,43,45,46,47,51] Terai and colleagues reported 2 patients with a congenital diverticulum of the right ventricle and a perimembranous ventricular septal defect.[46] The right ventricle was hypoplastic in one of their 2 patients, and thus at the time of surgical repair of the ventricular septal defect, the diverticulum was not resected. In their review of the literature, they concluded that two-thirds of the reported cases were not true diverticula, but in fact were fibrous aneurysms. Rarely, a patient will be found to have diverticula originating from both ventricles. Bandow and his associates described a 45-year-old man with apparently a congenital diverticulum originating from both the right and left ventricles.[55] Bogers and colleagues described the unusual findings of right and left ventricular diverticula in a patient with Cantrell's syndrome.[51,55,88,102,104,108,109,114,128] Fatal spontaneous rupture of a congenital diverticulum of the right ventricle was responsible for sudden death of a 1-month-old infant with type 1 truncus arteriosus. This outpouching from the free wall of the right ventricular outflow tract was characterized as a congenital fibrous diverticulum.[45] A similar case with a fatal outcome was reported by Farnsworth and colleagues in 1972.[18A] A right ventricular diverticulum in a neonate with severe congestive cardiomyopathy was documented by Laperal in 1994.[56] Two muscular aneurysms of the right ventricle have been recognized in 1 patient. Two of our patients with a large right ventricular diverticulum had associated ventricular septal defects, and in 1 of these patients, fibromuscular left ventricular outflow tract obstruction. There is little clinical information on which to base the decision for intervention. In at least 1 patient investigation of chest pain led to the recognition of the right ventricular diverticulum, and its resection alleviated the pain.[48] In other patients, resection or marsupialization was performed at the time of repair of associated cardiac defects.[39,40,41,43,46] When the diverticulum or aneurysm contracts synchronously with ventricular myocardium, and when serial MRI studies demonstrate no change in size, one can take a conservative posture. In this regard, serial MRI investigations are probably the best imaging modalities to assess and follow patients with aneurysms originating in the atrium or ventricle.[48,49] Paradoxical motion of the right ventricular diverticulum is perhaps more cause for concern, suggesting that the structure is likely thin-walled, fibrous and devoid or nearly so of normal myocardium.[45,48,49] One would also be concerned by the appearance of a right ventricular diverticulum with a very narrow neck as this area may be able to develop disproportionately high systolic pressures. In any patient with a cardiac diverticulum, one should be especially sensitive to adverse neurologic episodes, perhaps indicative of thromboembolic events. Similarly, cardiac palpitations, documented ventricular dysrhythmias, or syncope should provoke concern and focus on the diverticulum as possibly causal.[49,54] Since spontaneous rupture with death has been documented, one must be concerned about the fate of these structures, especially when coexisting cardiac lesions promote high right ventricular pressures. John and colleagues have published the fetal ultrasound of a patient with a right ventricular aneurysm.[54A] This patient had associated supraventricular tachycardia with left bundle-branch block aberrancy. They speculated that this patient could have an atypical presentation of arrhythmogenic right ventricular dysplasia.[54A]

Left atrial aneurysms

An extensive literature defining the clinical features and radiologic/angiocardiographic appearance of the aneurysm of the left atrium has accumulated over the past two decades.[10,57–83] It is of interest that these lesions of the left atrium almost uniformly have been referred to as aneurysms of the left atrium, not diverticulum. These aneurysms considered congenital in origin take their origin from the atrial appendage as well as the atrial wall

itself, although origin from the left atrial appendage is far more common.[64,66,83] Aneurysmal dilatation of the left atrium is frequently associated with mitral valve disease, and this condition is usually recognised in the third and fourth decades of life.[64,69,73] Stone and colleagues and Behrendt and Aberdeen reported an isolated aneurysm of the left atrium in a 5-month-old and a 10-month-old infant respectively, clearly indicating a congenital origin.[64,74] Cabrera and colleagues have reported the peculiar findings of a newborn infant with an aneurysm of the left atrial appendage, ascending aorta and sinus of Valsalva associated with a ventricular septal defect, fibromuscular subaortic stenosis and single coronary artery.[63] The recognition of a left atrial aneurysm has been based on an abnormal chest radiograph, echocardiography, angiocardiography, computerized axial tomography, or magnetic resonance imaging, these investigations often performed in the investigation of supraventricular rhythm disturbances, chest pain, embolic phenomenon, or an abnormal cardiac silhouette.[57–83] In the differential diagnosis of aneurysmal dilatation of the left atrial appendage, a congenital defect of the left pericardium should be considered.[71,72,76,85] It has been suggested that herniation of the left atrial appendage through such a defect may cause it to distend.[57] This association between congenital left atrial aneurysm and partial absence of the left pericardium has been stressed as well by Vargas-Barron and colleagues.[71] These authors indicate the potential difficulty in differentiating between these two conditions. This differentiation is of course important because of the possibility of strangulation of the left atrial appendage in a small left pericardial defect.[72] The etiology of idiopathic left atrial aneurysm or atrial diverticula is unknown. Accorsi and colleagues advance the hypothesis that idiopathic atrial dilatation could be due to a degenerative process affecting the atrial components derived from primitive atria, in which the muscular layer is structured into pectinate muscles.[79] They also distinguish, even from the etiopathogenetic point of view, between aneurysmal dilatation (localized and fortuitous lesion) and generalized dilatation (diffuse degeneration of pectinate muscles). This distinction could well be related to the different outcomes of atrial arrhythmia in the two types of dilatation.

Surgical resection of the left atrial aneurysm has been necessitated by chronic rhythm disturbances, thromboembolic phenomenon, and a changing size of the aneurysm. In some asymptomatic patients where serial imaging has not demonstrated a progressive change in the size of the aneurysm, a "wait and see" approach has been taken. It is likely that most of these patients will eventually require surgical intervention. Whether these patients before surgical resection (? or after) should be fully anticoagulated or placed on an anti-platelet factor is unclear.

Left ventricular diverticulum and aneurysms

It has been suggested that the congenital left ventricular diverticulum or aneurysm constitutes about 0.05% of all congenital heart malformations. A muscular left ventricular diverticulum can originate from either the cardiac apex or base.[10,84–129] When the diverticulum originates from the apex of the left ventricle, it is often associated with a midline thoracoabdominal defect; i.e. the Cantrell–Ravitch syndrome.[51,55,88,102,104,108,109,114,128] This syndrome is characterized by midline supraumbilical wall defect, cephalocaudal sternal wall shortening, deficiency of the anterior portion of the diaphragm, a congenital pericardial defect, intracardiac abnormalities and frequently cardiac malposition. A pulsatile mass in the relatively superficial epigastrium is very suggestive of this unusual constellation of visceral and cardiac anomalies.[51,55,88,102,104,108,109,114,128] When the left ventricular apical diverticulum is associated with an abdominal wall defect, the diverticulum protrudes inferiorly and forward into the epigastrium through a midline hernia sac and it is contained within a serous sac that is continuous with the pericardium. The diverticulum freely communicates with the left ventricular cavity, and contracts synchronously with the left ventricle. Other left ventricular diverticula may occur singly or multiply from the diaphragmatic surface of the left ventricle, may be muscular or fibrous, and thus may contract synchronously or paradoxically. Kato and his colleagues found 2 such cases amongst 3000 left ventriculograms.[89] The aneurysms usually have a wide orifice of communication with the true left ventricular chamber. While many such aneurysms of the left ventricle are considered congenital in origin, some being recognized from fetal echocardiography, there is a wide spectrum of etiologies including ischemic/infarction, traumatic, inflammatory, sarcoid, cardiomyopathy, etc.[1,2,7,8,105–107] The recognition of those aneurysms/diverticula not associated with midline thoracoabdominal defects may be incidental to evaluation of a ventricular rhythm disturbance, other structural or congenital cardiac anomalies, from echocardiographic and angiocardiographic evaluation of possible ischemic heart disease or a primary cardiac muscle disorder.[59] Some ventricular aneurysms are calcified, and others have been recognized in the setting of hypertrophic cardiomyopathy or Ebstein's anomaly of the tricuspid valve.[105] In those patients with so-called apical left ventricular aneurysm or diverticulum in the setting of hypertrophic obstructive cardiomyopathy, one must exclude mid-cavity obstruction.[105,106] We have studied 2 patients with a large left ventricular diverticulum producing the image of a bifid left ventricle. Both patients had some features of a congestive cardiomyopathy, but 1 could not implicate an ischemic etiology.[10] Certainly some left ventricular aneurysms in infants and children have a clear-cut ischemic basis, including those patients with an anomalous left coronary artery from the pulmonary trunk; infantile coronary calcinosis, or a sequela of Kawasaki disease. In other patients, the left ventricular aneurysm clearly has its origin in an inflammatory etiology. The appearances of the left ventricular diverticulum or aneurysms are diverse. Some are tiny and multiple, but do not require intervention. Others are dealt with at the time of repair of associated cardiac malformations in the setting of Cantrell's syndrome. Some fetal left ventricular aneurysms and those identified in the neonates will remain stable and perhaps as the left ventricle remodels, they may become less conspicuous. As with other forms of cardiac diverticula and aneurysms, the indications for surgical intervention are "soft." Clearly an enlarging aneurysm, one associated with important ventricular arrhythmias, and paradoxical motion of the aneurysm may be indications for intervention. Paradoxical motion of the aneurysm may suggest that the aneurysm is thin-walled and fibrous, and thus may be at risk for spontaneous rupture.

Subvalvar aneurysms of the left ventricle constitute a rare form of heart disease first described in the Black African, and then also found in other tropical parts of the world, i.e. South America and India.[130–139] These aneurysms are submitral or subaortic, sometimes congenital and originating in the aortic–mitral fibrosa, or what is termed now the attenuated left-sided

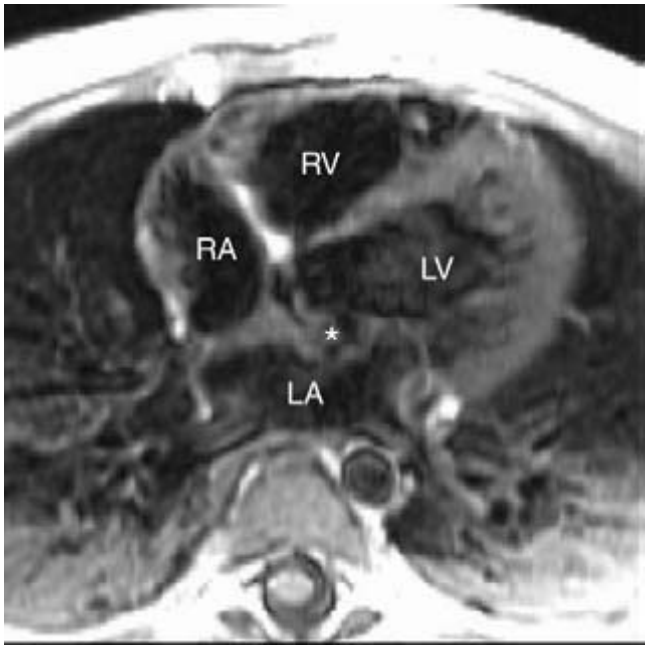

Fig. 39-2 Aneurysm of the central fibrous body. An aneurysm (asterisk) arises from the junction between the aortic and mitral valves and projects into the left atrium (LA). LV, left ventricle; RA, right atrium; RV, right ventricle.

ventriculoinfundibular fold (Fig. 39-2).[140–142] These aneurysms are non-ischemic and are of unknown etiology. Clinical recognition is difficult, as symptoms and findings are non-specific including tachyarrhythmias, systemic embolism, and mitral regurgitation.[88–92] The recognition is facilitated by echocardiographic and angiocardiographic imaging. Normann documented a subvalvular aneurysm in a 34-year-old black woman that had developed beneath the left coronary cusp of the aortic valve and extended in the epicardium between the aortic root and left atrium.[116] This woman was asymptomatic until she expired suddenly from myocardial ischemia caused by compression of the circumflex coronary artery by the aneurysm. A review of the literature conducted by this author revealed 13 reports of subaortic and 58 submitral aneurysms but only two instances of myocardial infarction secondary to coronary artery compression by spontaneous subvalvular aneurysms in either the subaortic or submitral position. Definition of this unusual expression of left ventricular submitral aneurysm has been made with transesophageal echocardiography and left ventricular angiocardiography. Because of the tendency for spontaneous rupture, adverse thromboembolic events and ventricular rhythm disturbances, most consider recognition of this entity an indication for surgery.[133–137]

Gelehrter and her colleagues have reported 9 children with left ventricular outflow tract pseudoaneurysms complicating congenital heart disease in 8 of these.[143] Seven of the 9 patients had left ventricular outflow tract pseudoaneurysms originating in the aortomitral intervalvular fibrosa and in 2 the pseudoaneurysm originated in the native right ventricular free wall following complex left ventricular outflow tract surgery. Seven of the 9 patients were asymptomatic on presentation. One baby with coarctation and a large ventricular septal defect was found at birth to have a left ventricular outflow tract pseudoaneurysm. This mass compressed the left atrium and pulmonary vein. This patient died at surgery. One other patient died late after repair likely due to myocarditis.[143] With the exception of the 1 patient with normal intracardiac anatomy, the others tended to have left-sided obstructive lesions.

Atrioventricular septal or valve diverticulum

In the investigation of a 63-year-old woman for severe aortic regurgitation, Lin and colleagues found a diverticulum or aneurysm of the atrioventricular membranous septum without any communication. This was demonstrated both by transesophageal echocardiography and left ventriculography.[125] Gerlis and his colleagues have recorded at post-mortem a diverticulum of the atrioventricular valve in a patient with right atrial isomerism.[126] This rare condition was not diagnosed during life. Finally, as stated earlier, the aneurysm of the membranous interventricular septum is rarely that, but rather tricuspid valve tissue adherent to the margins of the perimembranous ventricular septal defect.[144]

Cardiac Tumors

While cardiac tumors are not truly congenital heart malformations, they are with increasing frequency being detected in the fetus. After birth their clinical presentation can certainly simulate congenital heart malformations. Considerable literature concerning cardiac tumors in infancy and childhood has accumulated summarizing the prevalence, histologic types, clinical presentation and outcome, and changing imaging algorithms.[1–50] We have previously reviewed our institutional and thus pediatric experience with cardiac tumors,[30] and have recently published a selected review of cardiac tumors in the pediatric age group stressing imaging algorithms.[51] This chapter will focus primarily on the cardiac rhabdomyoma and fibroma, the two most common cardiac tumors in the pediatric population.

The ability to detect cardiac tumors non-invasively has led to an apparent increase in this diagnosis.[25,30] It is unlikely that this increase reflects a true increase in incidence or prevalence, but rather a manifestation of changing diagnostic/imaging practice.[29–51] This apparent increase in the diagnosis of cardiac tumors has been noted by the Mayo Clinic as well.[25] While for many years, cardiac angiography was considered the "gold standard" for the diagnosis of cardiac tumors,[11,50] today, cardiac ultrasound, computerised tomography and magnetic resonance imaging have largely supplanted invasive imaging.[29–49] Cardiac angiography including selective coronary arteriography may be required to define coronary arterial involvement/compression by the cardiac tumor.[50] However, as one reflects on the nature of cardiac imaging in the diagnosis of cardiac tumors, it is evident that echocardiography has emerged as the current primary diagnostic modality.[31–37] Its non-invasive nature has allowed for earlier detection in asymptomatic patients. Delineation of tumor location and extent and tissue characterization by magnetic resonance imaging have been important advancements.[36A] Tranesophageal echocardiography provides superior image quality and readily visualises the left atrial appendage, superior vena cava and the anterior surface of the heart.[31–37] These areas are less readily imaged from transthoracic echocardiography. In the future dynamic three-dimensional echocardiography may provide exact spatial information in intraoperative views. Finally, computerized tomography and magnetic resonance imaging provide complementary information about intra- and pericardiac masses in the pediatric population.[38–49]

Incidence

Data from the New England Regional Infant Cardiac Program showed of 2251 infants surveyed by this program with congenital heart disease, 11 had cardiac tumors, including 2 mediastinal tumors, 3 pericardial, and 6 cardiac tumors.[26] Primary heart tumors are uncommon in all age groups, with an incidence of 0.0017% in a large autopsy series reviewed by Straus and Merliss.[27] Nadas and Ellison reviewing the large pediatric experience of the Boston Children's Hospital cited a frequency of 0.027% among 11 000 pediatric autopsies.[22] These studies were all carried out before the routine application of cross-sectional echocardiography. Data published from our institution showed that from 1980 to 1995, 27 640 patients from fetuses to 18 years of age were referred or assessed for cardiac disease, and 56 of these had primary cardiac tumor.[30] The mean age at diagnosis of these patients was 27 ± 40 months, with the median age at diagnosis 4.7 months, ranging from 0.03 to 204 months. More than 50% were < 1 year of age at the time of diagnosis, with 10 patients diagnosed in the first month of life and 8 in the first week. A prenatal diagnosis was made in 12 patients.

The cardiac rhabdomyoma

As summarised by Becker, the presentation of the cardiac rhabdomyoma is diverse, leading in some to stillbirth or perinatal death.[52] In other patients clinical findings are dominated by cardiomegaly, congestive heart failure, cardiac rhythm disturbances and less commonly by sudden unexpected death. The clinical impact may be in large part determined by the tumor size, its or their location and whether or not they expand into an atrial or ventricular cavity, and whether the tumor mass obstructs the ventricular inflow or outflow. Cardiac rhabdomyomas tend to be multiple although solitary tumor masses have been described (Figs 40-1, 40-2).[52–126] The cardiac rhabdomyoma is a benign tumor of cardiac myocytes. It is considered by some a hamartoma occurring exclusively in the heart, often as multiple nodules composed of altered myocytes with large vacuoles and considerable glycogen. Observations about the regression process lend support to the fact that the cardiac rhabdomyoma is more likely neoplastic in origin rather than being a hamartoma.[76] The specific cell type that gives origin to the cardiac rhabdomyoma is still the subject of scientific debate,[63,104] although many believe these tumors have a myocardial origin, possibly representing aberrant development of cardiac myocytes.[63,76]

Cardiac rhabdomyomas occur in three clinical groups: (1) with tuberous sclerosis (30–50% of cases); (2) as sporadic lesions; (3) rarely in association with congenital heart malformations.[52–120] They have similar gross appearance in these settings; however, with tuberous sclerosis the rhabdomyomas are

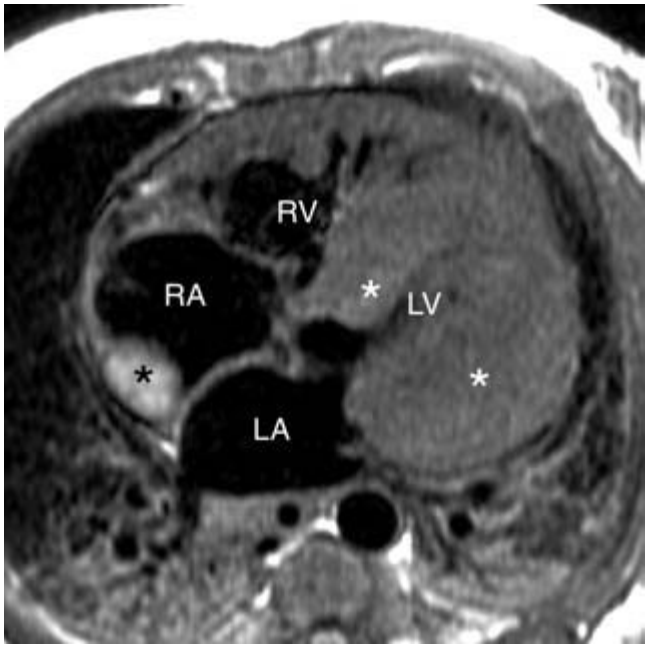

Fig. 40-1 Rhadomyomata in a young neonate. T1-weighted MR image in axial view shows multiple tumors (asterisks). The high signal intensity of the right atrial tumor around the crista terminalis suggests hemorrhage. The patient developed arrhythmia. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

usually multiple. The lesions vary from 1 mm to 10 cm in diameter. They most often occur in the ventricles but can be found in the atria, at the cavoatrial junction and on the epicardial surface.[63,104] Large lesions can obstruct outflow or inflow tracts.[10,11,30,50,54,57,59,60,67,76,78,79,86,87,91,92,98,104] Small lesions can involve the conducting system causing dysrhythmias.[10,30,43,65–67,72,85,91,92,100] The tumors are lobulated, tan-white, and often have a glistening watery cut surface. Hemorrhage and calcification are rare.[104] Sporadic rhabdomyomas more often are larger than those seen with tuberous sclerosis.

Multiple rhabdomyomas have been observed in identical twins,[118] a most unusual occurrence. Molecular genetic advances are likely to shed light on the etiology of cardiac tumors, whether or not associated with the phakomatoses.[121,122]

The tuberous sclerosis complex

Cardiac rhabdomyoma is often associated with the tuberous sclerosis complex (TSC) (Fig. 40-1).[51–103,108–110,114–117] The TSC is an autosomal-dominant disorder with a high mutation rate, characterized by the widespread development of distinctive tumors termed hamartomas. affecting brain, heart, skin, kidneys, and other organs. TSC-determining loci have been mapped to chromosomes 9q34 (TSC1) and 16p13 (TSC2).[51] The TSC1 gene was identified from a 900-kb region containing at least 30 genes. The 8.6-kb TSC1 transcript is widely expressed and encodes a protein of 130 kDa (hamartin) that has homology to a putative yeast protein of unknown function. Thirty-two distinct mutations were identified in TSC1, 30 of which were truncating, and a single mutation (2105delAAAG) was seen in 6 apparently unrelated patients. In 1 of these 6, a somatic mutation in the wild-type allele was found in a TSC-associated renal carcinoma, which suggests that hamartin acts as a tumor. More specifically, the tuberous sclerosis syndrome or complex is characterized by intracranial hamartomas, facial angiofibromas, subungual fibromas, linear epidermal nevi, renal angiomyolipomas, and other hamartomas. The necropsy study published some years ago by Fenoglio reported a 30% incidence of cardiac rhabdomyoma in patients with tuberous sclerosis, and clinically the association

may be as high as 50%.[63] The cardiac rhabdomyoma tends to be multiple, indeed they are multiple in > 90% of patients, *frequently involving* the interventricular septum, the walls of the heart, appearing as filling defects in the cavities of both ventricles, with a special predilection to involving the left ventricular outflow tract. These tumors may interfere with cardiac filling, and tumors approximating the tricuspid valve have simulated tricuspid atresia and those obstructing the mitral inflow have simulated mitral atresia and the hypoplastic left heart syndrome. Subaortic stenosis has been a common finding in the infant with cardiac rhabdomyomata, with pedunculated tumors in the subaortic vestibule. Superior or inferior caval vein obstruction is well recognized in the baby or young infant with cardiac rhabdomyoma. Patients with cardiac rhabdomyomas may present with almost any type of atrial or ventricular dysrhythmia, including pre-excitation, sinus node dysfunction and heart block. Fetal dysrhythmias or hydrops may be the presenting features in some patients with cardiac rhabdomyoma. Indeed, fetal recognition of multiple cardiac tumors has been considered suggestive of the tuberous sclerosis complex.[45,46,64,69,78,94,95,102,123,124,125] Cardiac rhabdomyomas are often diagnosed in the first year of life, and there is now increasing experience with fetal recognition of these tumors. Rarely, complex congenital heart disease may be associated with multiple cardiac tubers as in the patient with the hypoplastic left heart syndrome reported by Watanabe and colleagues[99] and other forms of congenital heart disease.[109,120] Other associations of the cardiac rhabdomyoma is with the basal cell nevus syndrome.[101] Rarely the fetal expression of cardiac rhabdomyomas is that of diffuse myocardial thickening.[102,115] One would not expect pericardial involvement with cardiac rhabdomyomas because of the origin of this tumor in the cardiac myocyte.

Spontaneous regression of cardiac rhadomyoma

One of the peculiar and puzzling aspects of these tumors is the observation of spontaneous regression.[10,29,30,43,52,58,75,91,92,100,126] This clinical phenomenon has now been extensively documented. We identified 44 patients with cardiac rhabdomyoma at the Hospital for Sick Children over the past 20 years.[91] Partial or complete regression of the rhabdomyomas was identified in 54% of the patients. The mean age at diagnosis for those patients whose rhabdomyomas regressed was 21 ± 30 months and the mean follow-up was 5.6 ± 3.0 years. Findings of tuberous sclerosis were observed in 18 of our 44 patients with rhabdomyoma (40.9%). Farooki and his colleagues reviewed the course of 4 neonates with 12 tumors.[62] All tumor masses except those in the right atrium demonstrated spontaneous regression. Indeed, there are ever increasing reports of spontaneous regression in these tumors. In cataloguing those tumors that tended to regress, Choi and colleagues have shown that complete regression occurred more frequently in younger patients and not surprisingly in those with smaller tumors.[92] Thus surgery is recommended only for those patients with severe hemodynamic compromise or for those with refractory dysrhythmias. One must realize that even with regression of cardiac rhabdomyomas, a substantial number of patients will still be disadvantaged by the cerebral and general organ involvement of tuberous sclerosis. In this regard it may be difficult to give a neurologic prognosis for the affected neonate. Data provided by Nir and associates reviewing the Mayo Clinic experience with cardiac rhabdomyoma showed that these tumors regressed both in number and size in most patients < 4 years of age.[100] Spontaneous regression in the fetus of cardiac rhabdomyoma has also been observed. Progression in size of these tumors secondary to corticotropin therapy has also been noted.[70,112] Corticotropin has been used to treat infantile spasms in these patients.

Those fundamental biological mechanisms governing spontaneous regression of the cardiac rhabdomyoma have not been defined, and clearly those mechanisms promoting selective cardiac apoptosis are intriguing.[76,76A] Wu and colleagues have studied the regression process of cardiac rhabdomyomas.[76] They found that that the cytoplasmic contents of the cardiac rhabdomyoma are degraded via the ubiquitin pathway, and this group observed increased TUNEL positivity, possibly explaining the mechanism of tumor regression or apoptosis. There are fewer data indicating spontaneous regression of cerebral involvement of tuberous sclerosis, and indeed spontaneous regression of cerebral tubers has not been seen. Thus the tragedy for many patients is the reality that spontaneous regression of the cardiac rhabdomyoma does not underscore well-being, as these patients may still be severely disadvantaged by cerebral and renal involvement, with the tendency towards malignancy in these areas. In this regard, Pipitone and colleagues identified nine cases of cardiac rhabdomyoma detected among 5276 fetal echocardiograms recorded over a 10-year period in a single center. The incidence of cardiac rhabdomyoma in this series was 0.17%. The gestational age at diagnosis ranged from 27 to 36 weeks. The most common reason for fetal echocardiography was an abnormal obstetric ultrasound scan (6/9 cases). In no case was there a family history of tuberous sclerosis. In one case, the tumor was single whereas in 8 cases multiple tumors were diagnosed. During prenatal life the majority of tumors were clinically silent. One fetus died of hydrops and arrhythmia. Four children presented with arrhythmia postnatally and one required surgery. At a mean follow-up of 47 months, total or partial regression was observed in 7 patients. Seven patients developed postnatal clinical signs of tuberous sclerosis.[112A] Others have also studied the prenatal and postnatal outcome of cardiac rhabdomyomas, with case reports showing tumor growth during the late stage of gestation.[45,54,69] It is of interest that Guntheroth and colleagues have documented spontaneous regression of myxoma-like tumors of the aortic or pulmonary valves in infants.[126A]

Cause of death in patients with tuberous sclerosis

The Mayo Clinic has reviewed the causes of death in patients with tuberous sclerosis.[105] Reviewing the fate of 355 patients with the tuberous sclerosis complex, their data showed a decreased survival when compared to the general population. The median age of their patients was 26 years, reflecting in part the referral nature of Mayo Clinic practice. They listed the causes of death related to renal abnormalities; brain tumors; cardiovascular involvement; lymphangio-myomatosis; bronchopneumonia; and status epilepticus. In this series, the most common cause of death was renal disease in the form of angiomyolipomas, cysts, or both. Subependymal giant cell astrocytomas occurred in 6% of patients. Pulmonary involvement is uncommon, occurring in < 1% of patients. The pathologic features are similar to those of lymph angiomyomatosis of the lung: cystic changes and focal lymph angiomyomatosis. Relatively few children and fetuses were encompassed in the Mayo Clinic

study and thus the survival curve is likely to be even more abnormal. Certainly patients with the tuberous sclerosis complex should be periodically screened for vascular aneurysms involving the thoracic aorta, the abdominal aorta and carotid artery amongst other sites. Some of these aneurysms have been noted to spontaneously rupture, causing death.[108,116,117] A wide range of cardiac arrhythmias have been documented in patients with cardiac rhabdomyoma, including ventricular arrhythmias and pre-excitiation.[72,83,85] Sudden death has also been attributed to these tumors.[105A]

Cardiac fibroma

The cardiac fibroma is the second most frequent cardiac tumor identified in the neonate and infant after the rhabdomyoma. The cardiac fibroma is a benign congenital tumor that occurs as a discrete bulging mass composed primarily of fibroblasts and collagen.[1–3,6,10,11,18,19,22,30,127–156] This tumor has also been called fibromatosis and fibroelastic hamartoma. The exact nature of the cardiac fibroma is unclear and there is ongoing debate as to whether the cardiac fibroma is a benign neoplasm or hamartoma.[106] This tumor is less common than the rhabdomyoma in the neonate and our institution has recognised less than 10 patients with cardiac fibroma in the past 15 years. Burke and his colleagues reviewed the files of the Armed Forces Institute of Pathology, identifying 23 cases of cardiac fibroma[135] The mean age at the time of diagnosis was 13 years, ranging from 1 day to 56 years. More than one-third of the patients were younger than 1 year of age at the time of diagnosis. This tumor, usually solitary, unlike the rhabdomyoma most often involves the left ventricular free wall or septum (Fig. 40-3). Rarely, more than one tumor is present,[153] and this can make differentiation from the rhabdomyoma more difficult. Involvement of the right ventricular free wall and cavity and the atria is less frequent, but is well described. The cardiac fibroma is not encapsulated and its tissue blends or infiltrates normal myocardium. Cut surface shows a bosselated or whorled pattern. Focal calcification is frequent and there is occasionally cystic degeneration. Both of these features are uncommon in the rhabdomyoma. They average 5 cm in diameter. Large lesions obstruct outflow tracts and compress cardiac chambers. Their growth is confined to the myocardial mass but they can incorporate proximal segments of coronary arteries precluding complete surgical removal. When they originate near or in the right atrioventricular groove, such tumor masses may compress the tricuspid inflow and may promote right-to-left intracardiac shunting in the neonate and young infant. The constituent cells of cardiac fibromas are spindled, monomorphic, and cytologically bland. In neonates and young infants tumors are cellular, may show mitotic activity, and have fibromyxoid stroma with variable numbers of collagen and elastic fibers. Collagen and elastin deposition increases and cellularity decreases with age. The tumor has an infiltrative border, surrounding and entrapping cardiac myocytes.

The tissue characteristics of the fibroma are considerably different than the rhabdomyoma, and thus non-invasive assessment with MR imaging can usually differentiate between fibroma and rhabdomyoma.[154–157] This tumor is benign, but continued slow growth may cause conduction defects, spread to the ventricular free wall, and may result in atrioventricular valve inflow or arterial outflow tract obstruction. Cardiac fibroma has presented in the neonate as severe congestive heart failure. Rarely this tumor may simulate cyanotic heart disease in the newborn because of septal and right ventricular involvement, promoting right-to-left shunting at atrial level. Two of the three neonates seen in our institution in the last decade presented in a state of cardiovascular collapse, were profoundly acidotic, had very weak peripheral pulses, and before application of cardiac ultrasound were considered to have the hypoplastic left heart syndrome or other expressions of diffuse left ventricular outflow tract obstruction. Spontaneous regression of the type seen in the patient with cardiac rhabdomyoma has not been

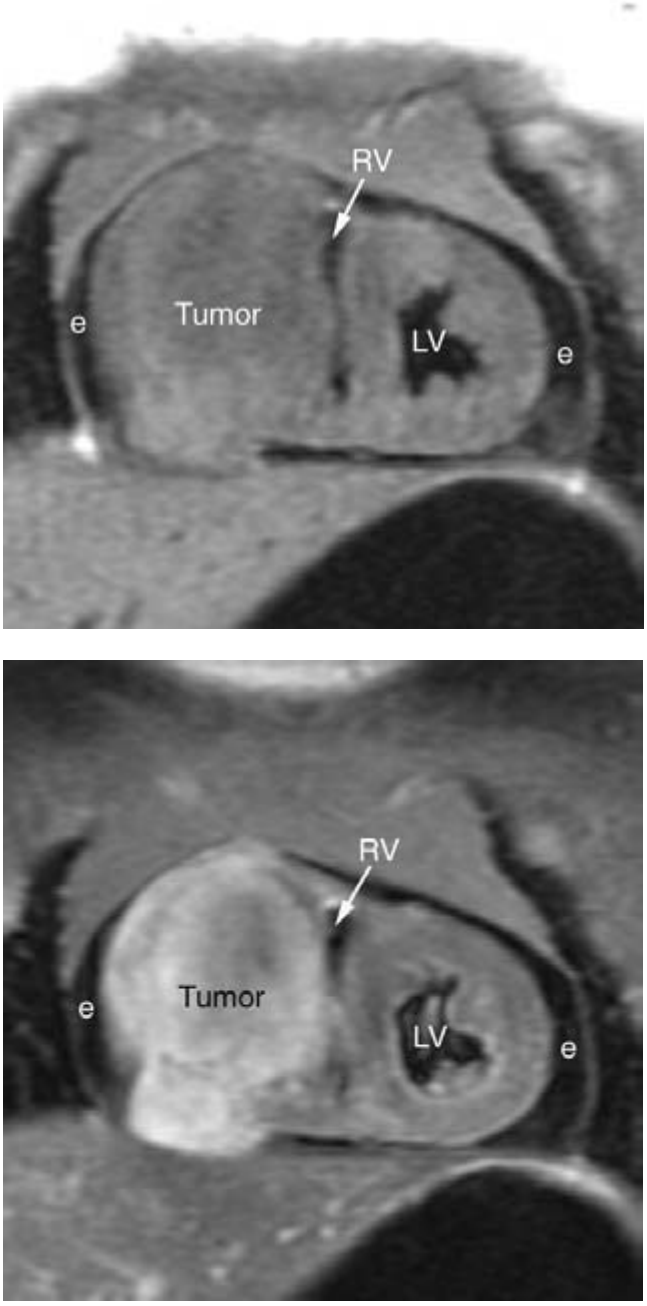

Fig. 40-3 Fibroma involving the right ventricular free wall. **A**. T1-weighted MR image in coronal plane shows a large tumor involving the free wall of the right ventricle (RV). The signal intensity of the tumor is similar to that of myocardium but a little heterogeneous. **B**. Contrast-enhanced T1-weighted MR image with fat saturation shows heterogeneous enhancement of the tumor. e, pericardial effusion; LV, left ventricle.

observed in the patient with cardiac fibroma, and operative intervention is usually required. One must remember that a massively hypertrophied ventricular septum in the newborn is not always neoplastic, but may represent a hypertrophic cardiomyopathy. Ventricular tachycardia and an abnormal cardiac silouette on chest x-ray in the infant and child may be considered presumptive evidence of a cardiac fibroma. The fibroma of the right or left ventricle may be partially or wholly resectable.[129,135,139,141,142,144,148,151,158,159] When the tumor often proves unresectable and cardiac transplantation has been performed in such patients, both in the pediatric patient as well as in the adult.[156,160] We have palliated two infants with a important right ventricular fibroma by partial resection, but we added a bidirectional cavopulmonary connection to provide a stable source of pulmonary blood flow and to unload the right ventricle.[149] Two neonates with huge left ventricular fibromas have undergone transplantation in our institution. Occasionally a neonate with a huge tumor will be asymptomatic and one can cautiously follow these patients.[150] The caveat in "wait and see" approach is of course the potential for sudden cardiac death.[152,161,162] Clonal translocation has been documented in the cardiac fibroma and some suggest that karyotyping should become a routine component of the characterization of cardiac tumors.[163,164]

Finally, myxomas, vascular tumors benign and malignant, teratomas, etc., may of course affect the pediatric patient.

Conjoined Twins

How does one begin a chapter on conjoined twins? We are all concerned by the ethical issues that such patients force on their parents and caregivers: "'Do we murder Mary to save Jodie?' An ethical analysis of the separation of the Manchester conjoined twins."[1] Or maybe: "Parents of Siamese twins appeal against separation."[2] And what about the cost to society – "'$1 million' treatment for Siamese twins re-ignites cost debate."[3] And to the heart of the matter: "Two hearts beating as one."[4] The titles of these papers are "catchy," and serve to focus our attention on most of the issues germane to these patients.

There is no doubt about it, conjoined twins are uncommon, with a prevalence suggested between 1:33 000 and 1:165 000 births, with Hansen's estimate of 1:50 000.[5–7] Some years ago, an epidemic of conjoined twinning was suspected in South Africa and Cardiff, although some disputed this report.[8,9] Conjoined twins are classified according to the area of union, the most common site of conjunction being the anterior thoracic and upper abdominal midline, such twins designated as thorapagus or thoracopagi.[5,6] Twins with thoracic union have a high incidence of cardiac anomalies.[5,6] They are considered the product of a single ovum and like separate monozygotic twins, they are of the same sex, presumably have identical genetic constitutions, with similar palmar and plantar epidermal characteristics. Conjoined twins have a striking female predominance (70–95%).[5–7, 10–19] This malformation of monozygotic twinning results when there is incomplete division of the single fertilized egg. The basic defect is an incomplete fission which takes place before the third week of ovulation age. Fortunately very rare, the impact of thoracopagus conjoined twins is not just conjunction of their livers, but of their hearts. From the numerous case reports and review of larger series in the literature of thorapacopagus conjoined twins, the impact of the cardiovascular junction is clearly the most serious, and disturbances in laterality are frequent.[5–7,10–23]

Thoracopagus twins are the most common of conjoined twins, accounting for about 75% of all conjoined twins. They are frequently born prematurely, or are stillborn, but there is increasing prenatal recognition and fetal diagnosis of the associated cardiac malformations.[24–29] The severity of the visceral malformations depends in large part on the extent of the area of union, and the pleural, pericardial, and peritoneal cavities may be common to both twins, or separate. In virtually all cases of thoracopagi, the livers are fused.[5–7,10–29] Somewhat surprising, despite the external symmetry of thoracopagi, their viscera are not necessarily identical, nor mirror-images of one another. Indeed, one twin has been identified with asplenia and lack of organ lateralization, while the other twin has had normally lateralized viscera.[10,21–23]

The cardiovascular systems

As summarized by Gerlis and his colleagues from their extensive examination of conjoined twins, the cardiovascular system in conjoined twins can be described on the basis of the number and nature of the heart(s) and their location within the body.[10] Some conjoined twins had a single heart, but in others partial duplication of cardiac elements forming a single cardiac structure was identified. Gerlis designated this latter arrangement as a compound heart. The situation is made even more complex by the topography of the heart within the twins. The sternum, heart, and spinal columns may be in a single plane, and the heart is then readily assigned to one or the other twin. In some of the twins, however, the heart(s) and sternum are arranged at right angles to the plane between the two spinal columns, and thus neither heart can be assigned to either twin, and these hearts are considered shared. The sternum is partially or wholly absent or deficient in thoracopagus conjunction. Data summarized by Edwards indicates that the pericardial sac was common to both twins in 90% of reported cases, and that fusion of the heart is found in 75%.[12] Three following types of cardiac fusion have been described: pericardial conjunction; atrial fusion with separate ventricles; and atrial and ventricular fusion. Considering the potential and indeed reality for such complex arrangements between the twins, this is probably somewhat of an oversimplification.[5–7,10–29]

The majority of babies with conjoined hearts exhibit complex ventricular anatomy, with one ventricle for both twins; two ventricles (single ventricle for each twin); three ventricles (one ventricle for one twin, and two for the other); and four ventricles. The majority of patients also have complex conotruncal malformations, with complex transposition; pulmonary atresia; truncus variants; hypoplastic left ventricle syndrome, etc. With atrial and ventricular fusion, the circulation is very complex and may be difficult to unravel even at the autopsy table. So-called "figure-of-eight" circulations have been described in babies with atrial and ventricular fusion.[30,31] The cardiac apices usually point in the opposite direction.[5,10,12,13] Rarely, the ventricular masses of conjoined twins may be contiguous, but non-fused, lending themselves to successful separation as in the case reported by McMahon and colleagues.[13A]

Right isomerism and left atrial isomerism have been described in thoracopagus twins, indicative of the tendency of symmetry both in external appearance and in the disposition of viscera so common to thorapagi.[10,21–23] Ursell and Wigger have described a set of thoracopagus twins who did not demonstrate this internal symmetry.[21] In this particular patient, one twin had

asplenia with disturbed laterality of viscera, while the other twin had a normally lateralized visceral arrangement.[21] Of the 6 cases with two conventional hearts in the review of Gerlis, no instance of disturbed laterality was found in both twins despite the finding of right isomerism of the heart of the right-side twin in one case and left isomerism of the heart of the right-side twin in one case.[10,21–23]

The diagnosis of conjoined twins is made with increasing frequency by fetal ultrasound. For the most part, invasive imaging for the investigation of the cardiac abnormalities in conjoined twins has been replaced by a combination of electrocardiography, cross–sectional echocardiographic and magnetic resonance imaging.[24–29,32–44] With complex venous anatomy and the potential for atrial and/or ventricular conjunction, cardiac catheterization with angiography may still be necessary.[32–46] Even in those conjoined twins without primary cardiac conjunction, a complex circulatory arrangement may jeopardize one twin at the expense of the other.[47]

Outcome analysis

Once the prenatal diagnosis of conjoined twins is firmly established, most families decide on termination of pregnancy.[27] Sanders has amply discussed those many factors contributing to successful separation of conjoined twins, and the difficult ethical and philosophical dilemmas posed by these children.[1–3,24,29] There has been some success in the separation of conjoined twins who share a common pericardial sac.[13,14,18,35,48] In one set of conjoined twins, ligation of an arterial duct was performed first, followed by successful separation.[49] Chiu and colleagues reviewed to 1994 the outcome of attempted separation of thoracopagus twins.[49A] In reviewing 47 pairs of surgically separated thoracopagus conjoined twins, in 30 pairs of type A (Leachman's classification, completely separate hearts), 42 patients survived (70%); in 5 pairs of type B (atrial connection only), one patient survived (10%); in 9 pairs of type C (both atrial and ventricular interconnections), none survived. The total survival rate of surgically separated thoracopagus conjoined twins was 47.9%. The survival rate was 38.2% in those operated in the neonatal period ($n = 34$) and 63.6% in those operated over 1 month of age ($n = 44$) ($P = 0.016$). But the most important consideration in terms of successful separation was the site or sites of pericardial or cardiac conjunction. Fishman and colleagues have reported cardiac relocation and chest wall reconstruction after separation of thoracopagus conjoined twins with a single heart. One twin survived.[50]

Finally, and unrelated to either conjoined thoracopagi or ectopia cordis, is that extremely rare condition of an infant with two "half-hearts."[51] This 5-day-old baby was found at autopsy to have two "half-hearts" totally separated from the other and each had a single atrium and ventricle. The two "half-hearts" were enveloped in a common pericardium. There were double truncus and double superior and inferior caval veins. The pulmonary venous drainage was totally anomalous, but there were no splenic abnormalities, and the viscera were normally lateralized. Finally, Anderson has provided documentary and artistic evidence for conjoined twins from 16th century England.[52]

Ectopia Cordis (Exteriorization of the Heart)

Ectopia cordis, so-called exteriorization of the heart, is an exceedingly uncommon condition, and can be considered one of the cardiac malpositions along with dextrocardia, mesocardia, conjoined thoracopagi, and the so-called "topsy-turvy" hearts.[1–4] This condition is characterized by complete or partial displacement of the heart outside the thorax.

Prevalence

Ectopia cordis occurs in *c*. 5.5–7.9 per 1 million live births.[1–4] There is only very rarely a familial tendency,[3A] but a number of patients with ectopia cordis and chromosomal abnormalities have been described.

Morphology

Ectopia cordis can be catalogued into four types: (1) cervical; (2) thoracic; (3) thoracoabdominal; (4) abdominal.[1–4] There is only one well-described case of an abdominal ectopia cordis. The cervical form of ectopia cordis is also a very uncommon form of this already rare disorder, and with rare exception is observed only in severely malformed fetuses. The thoracic and thoracoabdominal forms constitute *c*. 97% of the cases of ectopia cordis.[3]

The classic expression of ectopia cordis is the thoracic form. The thoracic form has an associated sternal defect, deficiency or absence of the parietal pericardium, cephalic orientation of the cardiac apex, an omphalocele, and a small thoracic cavity. The thoracoabdominal form of ectopia cordis has received considerable attention, and this form is usually associated with congenital heart malformations.[1–4] In addition to the usually associated cardiac malformations, this type of ectopia cordis is associated with a distal cleft sternum; an omphalocele-like ventral abdominal defect; a midline anterior diaphragmatic defect; and a free pericardioperitoneal communication, the combination being called Cantrell's pentalogy or pentad.[2]

Associated malformations

Amongst those patients with the thoracic or thoracoabdominal forms of ectopia cordis, many forms of congenital heart disease have been identified, including ventricular septal defect, single ventricle, double-outlet right ventricle, and infundibular atresia.[1–14] The more important extracardiac malformations contributing to poor outcome include a large omphalocele and pulmonary hypoplasia. A number of chromosomal abnormalities have been defined in the patient with ectopia cordis.[15–17] Ventricular diverticulum is well recognized in some patients with ectopia cordis[2,3,5,6,14] (see also Chapter 43).

Outcome

There is increasing experience with fetal diagnosis of thoracic ectopia cordis, but when recognized prenatally, many families decide to terminate the pregnancy.[1,5,18] Of the 5 cases of ectopia diagnosed prenatally in the series reported in 2000 by Hornberger, 4 families elected termination of pregnancy.[18] Humpl and colleagues have reviewed the experience of the Toronto Hospital for Sick Children with ectopia cordis.[5] Between 1978 and 1998, 10 patients with ectopia cordis presented to this institution. Three had normal intracardiac anatomy and the remainder had mild to complex structural heart disease. Associated noncardiac malformations were diagnosed in 6 patients. Prenatal ultrasound diagnosed 6 instances of ectopia cordis in fetuses between 19 and 37 weeks of gestation. These pregnancies were either electively terminated or the infants died shortly after birth. Four other babies with ectopia cordis were referred to our institution and died either at the time of surgery for the cardiac or noncardiac anomalies. Hornberger when in Boston and her colleagues reported on the outcome of 13 infants with ectopia cordis and significant heart malformations seen from 1982 to 1996.[6] Four of these 13 had thoracic ectopia cordis and 9 thoracoabdominal. The diagnosis was made *in utero* in 6, with termination of pregnancy in 2 and death before transfer to the Children's Hospital in one. Of the 10 patients postnatally managed at the Children's Hospital, 4 of 8 with thoracoabdominal ectopia cordis and 1 of 2 with thoracic ectopia cordis survived beyond infancy. Three patients underwent complete repair of the cardiac defects, and 2 underwent single ventricle palliation. None of the 5 survivors had significant extracardiac defects, whereas all 3 who died by 3 weeks of age had both a large omphalocele and pulmonary hypoplasia. Thus as one surveys this substantial series and other case reports in the literature, there have been some surgical successes. but because of the associated cardiac malformations and propensity for infection, survival is still uncommon.[2,5,6,9,14,19–23] However, at least 1 patient with thoracoabdominal ectopia cordis and a univentricular heart underwent a successful three-stage Fontan procedure, a right-modified Blalock–Taussig shunt at the age of 1 month, bidirectional Glenn shunt and pulmonary arterioplasty at 2 years 8 months, and finally a total cavopulmonary connection at 4 years.[24] Another patient with tricuspid atresia, currently with a balanced circulation, has undergone successful repair of ectopia cordis and is scheduled for single ventricle-Fontan palliation.[25] Some have reported excellent outcomes for patients with ectopia cordis and congenital heart disease.[26]

Idiopathic Arterial Calcification of Infancy

Idiopathic arterial calcification of infancy is a very uncommon disorder of unknown etiology that is characterized by diffuse arterial calcification, and with rare exception is fatal in infancy.[1,2] First likely described by Bryant and White in 1891,[3] the earliest major review of this disorder was published by Stryker in 1946.[4] Rosenthal mentioned that by 1966 > 50 patients had been reported,[5] and by the millennium, the number is considerably more. The cause of death in most affected patients is invariably related to severe coronary arterial calcification and the resulting myocardial ischemia and infarction.[1,2,5–15] Rarely, the disorder presents later in childhood as in the 11-year-old girl reported by Sebire and Sheppard.[11A]

Prevalence and genetics

This is a very rare disorder and most even very large centers see only a few cases over many decades. There is a well-known familial predilection and a number of sibships have been reported.[1,2,5,6,10,15–21]

Pathology of idiopathic arterial calcification of infancy

This is a disease that begins and has been recognized in the fetus.[22–28] This disorder involves the coronary arteries, as well as the carotid, renal, retinal and other medium sized arteries.[1,2–21] According to Hoffman, the coronary arteries are involved in 90% of patients and renal, pancreatic and splenic arteries in 50% of patients.[1] It is unclear whether idiopathic arterial calcification is a single pathological process or several that overlap with a similar end result.[1,2] The pathological process is uneven and in the same patient, intimal fibrous proliferation dominates in some sections of muscular arteries, while in others, fragmentation of the internal elastic lamina with deposition of calcium is the more conspicuous finding.[1,2,5–7,19,21] Intimal connective tissue proliferates and occludes the vessels, contributing to coronary, myocardial, and renal ischemia, etc. Rarely, there are findings consistent with an inflammatory arteritis,[29,30] and in other patients intimal proliferation is minimal.[31]

Outcome analysis

This disease has been recognized in the fetus and the affected fetus often demonstrated pleural hemorrhage, hydrops and polyhydramnios.[22–28,32] The diagnosis of idiopathic arterial calcification can be made by palpation of the firm, rigid superficial arteries in the neck and limbs [1,2,5,6] and by imaging of the calcified arteries with plain x-ray, CT scan, and MR imaging.[1,2,5,6,33–36] The majority of affected patients present in infancy with congestive heart failure within the first few months of life, many with findings of myocardial infarction.[1,2,5,5–21] A few patients may present with hypertension, reflecting involvement of the renal arteries.[37,38] Other young infants may present with bowel ischemia, severe hepatic involvement suggesting Reye's syndrome, and infrequently cerebrovascular pathology will dominate the clinical picture.[18]

Survival into adulthood is distinctly uncommon, but this has been reported as has intermediate-term survival.[39–41] In an occasional patient, peripheral vascular insufficiency may dominate the clinical picture.[42] There has been some success with the therapeutic use of bisphosphonates, but this has not been universally effective.[1,2,10,14,17,20,27,39–41,43] Sholler and his colleagues have also reported 3 patients, 1 demonstrating spontaneous regression of calcification.[15]

Persistent Fifth Aortic Arch

The persistence of the fifth aortic arch is an uncommon congenital heart malformation in humans (Figs 41D-1, 41D-2). In the past, its existence has been a matter of embryologic dispute, because in Mammalia the fifth pharyngeal pouch develops poorly and the associated fifth branchial artery was considered to be similarly indistinct and evanescent by authors such as Balinsky,[1] Arey,[2] Langman,[3] and Duckworth.[4] Yet the descriptions of Huntington[5] and Brown[6] in the cat embryo, and Buell[7] in the chick embryo, led to the conclusion of the definitive existence of the fifth aortic arch in Mammalia. Moreover, in his classic study of the transformation of the aortic-arch system during the development of the human embryo, Congdon,[8] convincingly confirms the occurrence of the fifth aortic arch in man. Two decades later, additional supporting evidence of the existence of the fifth branchial arch was found by Kramer[9] in a 13-mm human embryonic specimen with a well-developed right fifth aortic arch.

In 1969, Van Praagh and Van Praagh[10] first described a case of persistent fifth aortic arch in an autopsy specimen, associated with tricuspid atresia, cor triatriatum, ventricular septal defect, infundibular and valvar pulmonary stenosis and a patent ductus arteriosus. Later, in 1973, Izukawa and colleagues[11] first reported the persistence of a left fifth aortic arch during life. Since then, a fifth aortic arch has been suspected or confirmed in association with numerous congenital heart abnormalities providing systemic to systemic, systemic to pulmonary and pulmonary to systemic arterial connections. The occurrences of a persistent fifth aortic arch in isolation[12,13] and its bilateral persistence[14] have also been described.

Incidence

The incidence of the persistent fifth aortic arch is unknown, greatly due to failure of recognition in many situations, as it has been called "the great pretender." Since a persistent fifth aortic arch presenting as double-lumen aortic arch itself is asymptomatic, some cases occurring as isolated developmental defects, may not be diagnosed. However, Gerlis and colleagues[15] estimated an incidence of *c.* 1 in 330 cases among 2000 congenitally malformed hearts in the combined collections of the Brompton and Killingbeck Hospitals, UK. At the Toronto Hospital for Sick Children seven patients were encountered, all associated with other congenital heart malformations.[11,16,17]

Embryology

The embryology of the aortic arch is best described as a sequential appearance and persistence or dissolution of paired vessels connecting the truncoaortic sac with the paired dorsal aorta, which eventually fuse to form the descending aorta (Fig. 41D-1). Each arch corresponds to a branchial pouch derived from the embryonic foregut, although all are not present at any one time. The first and second brachial arches are first to form and first to disappear. The third branchial arches enter into the formation of the carotid arteries. The segment of the paired ventral aortas between the third and fourth arches represent the right or left common carotid arteries. The fifth pairs of arches regress early but may persist (Fig. 41D-2). In the normal development of the arterial pole of the heart, only two of the six primitive aortic arches, the fourth and sixth, persist to join the ventral and dorsal aorta. The fourth becomes the definitive aortic arch, and the formation of a right or left aortic arch requires regression of the right or left dorsal aortic root respectively. If both persist, double aortic arch is present. The definite right and left pulmonary arteries are formed from the proximal portion of the paired sixth branchial arches. The distal portion of the sixth arches becomes the right and left ductus arteriosus. The persistence of both distal portions of the paired sixth branchial arches leads to the presence of bilateral ductus arteriosus. Early in development, the dorsal aortic roots originate intersegmental arteries that supply the spinal cord and developing somites. The seventh intersegmental artery on each side will migrate between the common carotid arteries and the ductus arteriosus, forming the right and left subclavian arteries.

Associated cardiac malformations

A persistent fifth aortic arch has been involved in a variety of cardiac malformations.[10–57] We have classified its occurrence as providing four different types of connections (Table 41D-1).

Type 1: Systemic to systemic arterial connections

Double-lumen aortic arch (also called "double-barrelled aorta" or "subway") was the first setting in which the persistence of the fifth aortic arch was described and the most frequent type encountered. The fifth arch is situated below the true aortic arch (fourth aortic arch) and extends from the level of the innominate artery proximally to the level of the subclavian artery and ductus arteriosus distally, with ostia at both ends that communicate with the aortic lumen. Embryologically, double-lumen aortic arch appears to result from persistence of both the fifth and the fourth branchial arches. It has been described with either left-[10,11,18,19] or right-sided[15,20–22] aortic arch and in isolation.[13] Associations with common arterial trunk,[15] tricuspid

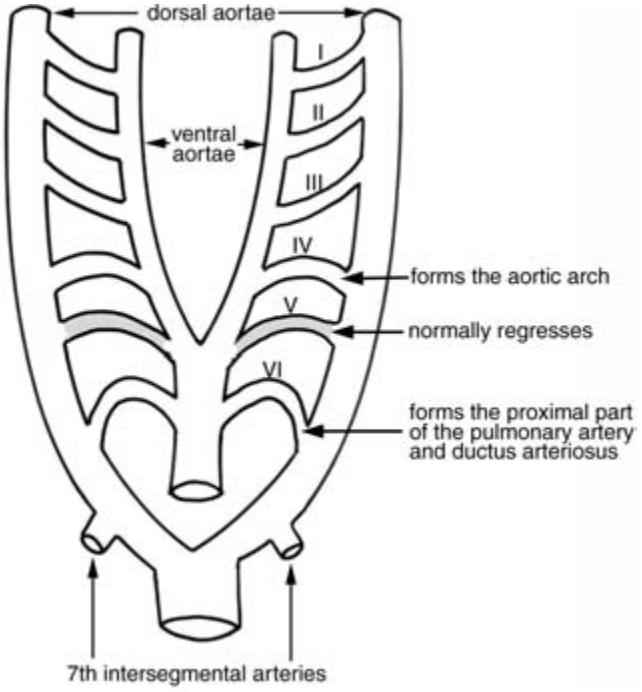

Fig. 41D-1 Development of the aortic arches. The aortic arch arises from the fourth aortic arch (IV) and the ductus arteriosus and proximal pulmonary artery arise from the sixth arch (VI). The persistence of the fifth arch (V) results in various abnormalities as shown in Fig. 41D-2.

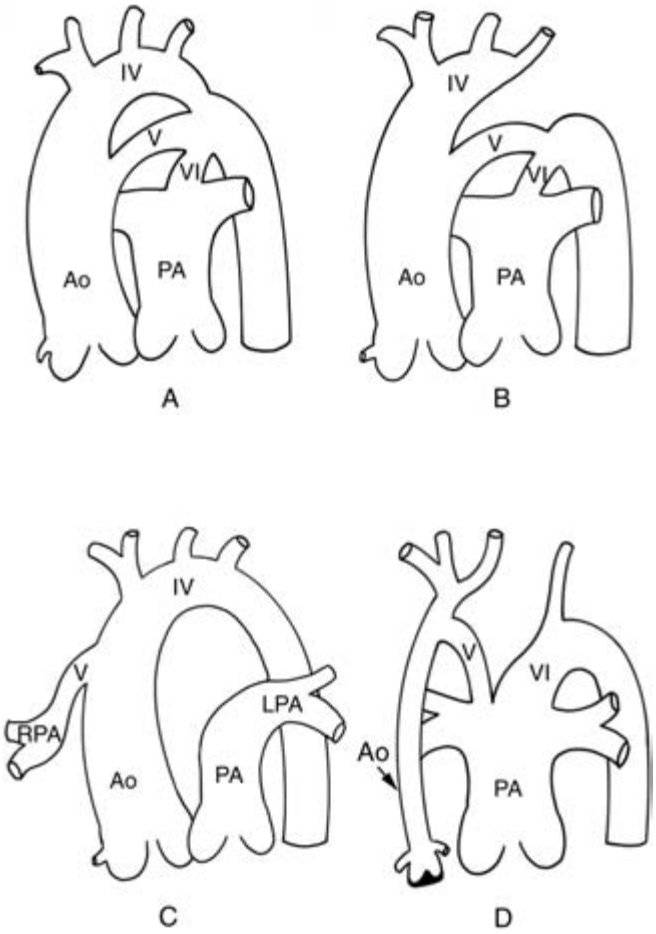

Fig. 41D-2 Examples of persistence of the fifth aortic arch (V). **A**. Double lumen aortic arch. **B**. The fifth aortic arch as the sole aortic arch channel. **C**. Origin of one pulmonary artery from the distal ascending aorta (Ao). **D**. The fifth aortic arch as the sole source of blood flow to the ascending aorta in aortic atresia with interrupted aortic arch. LPA, left pulmonary artery; PA, pulmonary artery; RPA, right pulmonary artery; IV, fourth aortic arch; VI, sixth aortic arch (ductus arteriosus).

atresia,[10,23,24] cor triatriatum,[10,23] pulmonary stenosis,[10,23] pulmonary atresia,[22,24] patent ductus arteriosus,[10,11,18,23] coarctation of aorta,[11,25–35,55,56] bicuspid aortic valve,[11] atresia of the distal part of the fourth arch (interrupted aortic arch),[21,25,26,29,32,33,55,56,57] single right coronary artery,[11] aortopulmonary window,[22] aneurysm of the left subclavian artery,[26] d-transposition of great arteries, ventricular septal defect and pulmonary atresia,[36] tetralogy of Fallot,[20,37,38] stenosis of the origin of the left subclavian artery,[21] double-outlet right ventricle, transposition of great arteries, patent ductus arteriosus and interruption of the fourth aortic arch,[34] bilateral superior caval vein,[22] secundum atrial septal defect,[19] pulmonary sequestration[21] and VATER association[13] have been reported. A patient prenatally exposed to the anticonvulsant drug trimethadione[18] associated with the presence of a double-lumen aortic arch, a patent ductus arteriosus and dislocation of the hip has been described. Chromosomal studies showed a karyotype of 46, XX, 9qh+.

There has been a rather more frequent association between a double-lumen aortic arch with coarctation of aorta and interrupted aortic arch. This might be a coincidental relationship but

Table 41D-1 Types of persistent fifth aortic arch

Type 1 Systemic to systemic arterial connection	Double-lumen aortic arch
	Origin of the subclavian artery as a first branch of the ascending aorta
	Origin of a collateral as first branch of the ascending aorta in pulmonary atresia and ventricular septal defect
Type 2 Systemic to pulmonary arterial connection	Associated with pulmonary atresia or an aortic arch anomaly
	Associated with a large left to right shunt without an associated great vessel anomaly and pulmonary hypertension
	Anomalous origin a branch pulmonary artery from the ascending aorta
Type 3 Pulmonary to systemic arterial connection	Associated with aortic atresia and interruption of the fourth aortic arch
Type 4 Combinations	Bilateral persistent fifth aortic arch

one possible explanation for this faulty development of the aortic arch could be explained by the fact that the normal blood supply to the ascending aorta in patients with this condition is divided between two channels, hence the blood flow to the fourth branchial arch is diminished leading to either coarctation or interruption of the aortic arch. Lim and colleagues reported the case of a 2-month-old girl with a common arterial trunk and coarctation of a persistent fifth aortic arch shown by computed tomography who underwent successful repair.[56A]

The origin of the subclavian artery as a first branch of the ascending aorta would appear to be very uncommon, with a few cases reported in the literature so far.[17–39] It may occur with either a left or a right-sided aortic arch. The first branch arising from the ascending aorta is the subclavian artery on the opposite side of the arch. Embryologically, it could be explained by the persistence of the fifth aortic arch and the disappearance of the ipsilateral fourth branchial arch as well as the segment of the dorsal aorta between the fourth and the fifth arches. Moreover, a cranial deviation of the seventh intersegmental artery on the opposite side of the aortic arch should occur, so the future subclavian artery would originate from the fifth instead of the fourth aortic arch. In this setting, the subclavian artery arises from the ascending aorta as a first branch prior to the ipsilateral common carotid artery. Both, separate and common origins of the left and right common carotid arteries have been encountered.[17,39,40,41] Associations with heterotaxy syndrome, complete atrioventricular canal defect, single right coronary artery, L-transposition of great arteries, double outlet right ventricle, supravalvar and valvar pulmonary stenosis, left superior vena cava, pulmonary atresia and an intact ventricular septum, and patent ductus arteriosus have been reported.[17] A patient with the subclavian artery as the first branch of the aortic arch and Fanconi's anemia has been encountered.[17]

A very unusual case of pulmonary atresia with a ventricular septal defect associated with systemic to systemic arterial connection provided by a fifth aortic arch was reported by Yoo and colleagues.[16] The fifth aortic arch arose from the distal ascending aorta on the opposite side of the aortic arch and was connected to a major aortopulmonary collateral artery, which in turn bifurcated to supply confluent pulmonary arteries as well as intrapulmonary arteries not connected to the pulmonary arteries. A left aberrant subclavian artery from a descending aorta diverticulum was present. A possible embryological explanation includes the regression of the left fourth aortic arch with persistence of the right fourth arch. The left dorsal aorta has been interrupted at two levels: one between the third and fifth arches, and the other, between the fifth arch and the left seventh intersegmental artery. The most distal segment of the left dorsal aorta has persisted and formed the root of the aberrant subclavian artery. A small segment of the dorsal aorta adjacent to the fifth arch has remained patent and it is from this that the collateral arteries extend to both lungs.

Finally, Lee *et al.*[42] reported a patient with microdeletion of chromosome 22q11, isolated infundibuloarterial inversion, right aortic arch and a remnant non-patent systemic to systemic arterial fifth aortic arch.

Type 2: Systemic to pulmonary arterial connections

Systemic to pulmonary arterial connections involving a fifth aortic arch have been reported with either right-[12,35] or left-sided[15,22,43,44] aortic arch. Associations with pulmonary atresia and ventricular septal defect,[22,35,45,46] pulmonary atresia with an intact ventricular septum[48] and right pulmonary artery interruption[46] have been encountered. A rare case where a persistent fifth aortic arch associated with an interrupted fourth aortic arch, a patent ductus arteriosus and a bicuspid aortic valve was reported by Gerlis and colleagues.[15] Three patients with diagnosis of anomalous origin of the left pulmonary artery from the ascending aorta[14,47] associated in all cases with a right aortic arch, a right patent ductus arteriosus and confirmed[14] or suspected DiGeorge syndrome[47] have been reported. Serra and his colleagues[48] described a patient with pulmonary atresia and intact ventricular septum with non-confluent pulmonary arteries, where the right pulmonary artery was supplied through a right-sided patent ductus arteriosus and the left pulmonary artery likely through a fifth aortic arch providing a systemic to pulmonary arterial connection. Freedom *et al.*[43] reported a case with tricuspid and pulmonary atresia, coarctation of aorta, hypoplastic transverse arch and a fifth aortic arch located on the same side as the definitive aorta giving a direct systemic to pulmonary artery connection. Another patient with pulmonary atresia, ventricular septal defect and a persistent fifth aortic arch was described by Macartney *et al*.[35] In this case, the pulmonary blood supply was derived both from several major aortopulmonary collaterals and from a persistent fifth aortic arch.

The majority of cases, in which a persistent fifth aortic arch has a systemic to pulmonary arterial connection, have either been cases of pulmonary atresia or an aortic arch anomaly. Patients with large left to right shunt due to a persistent fifth aortic arch without an associated great vessel anomaly and pulmonary hypertension have also been reported.[12,44]

Type 3: Pulmonary to systemic arterial connections

A persistent fifth aortic arch giving a pulmonary to systemic arterial connection is extremely rare. Four cases with this type of connection have been encountered. In all of them the dominant lesion was aortic atresia with an interrupted aortic arch, and the fifth aortic arch supplied the ascending aorta and the coronary arteries.[15,49,49A,50] Donofrio[49] and De Caro[49A] and colleagues reported one patient each with similar findings: aortic atresia, interrupted aortic arch and an "aortopulmonary fistulous tract" communicating the main pulmonary artery with the ascending aorta. This fistulous tract supplied the ascending aorta and coronary arteries. While the authors did not suggest this fistulous tract to be a fifth aortic arch, in retrospect it likely is this structure. Another patient[50] with aortic atresia, hypoplastic mitral valve and left ventricle, interruption of the aorta proximal to the brachicephalic artery and a persistent fifth aortic arch communicating the hypoplastic ascending aorta and the pulmonary trunk has been encountered. A restrictive left-sided patent ductus arteriosus was also present. Gerlis and colleagues[15] reported another case with aortic atresia, interrupted left aortic arch, aberrant right subclavian artery, bilateral superior vena cava, an inlet ventricular septal defect, a left-sided patent ductus arteriosus and a right-sided fifth aortic arch connecting the right pulmonary artery and the ascending aorta.

Type 4: Combinations

Bilateral persistent fifth aortic arch has been found in a patient with double-lumen aortic arch and anomalous left pulmonary

artery origin from the ascending aorta.[14] In this case, double outlet right ventricle with a subaortic ventricular septal defect, subvalvar and valvar pulmonary stenosis, right aortic arch, and a right-sided patent ductus arteriosus were present. Due to the associated facial anomalies, a conotruncal anomaly was suspected.

In some cases[51] there has been dispute about the presence of a persistent fifth aortic arch versus the persistence of the distal part of the sixth arch as patent ductus arteriosus.[52] Recently, Peirone and colleagues[53] reported a patient with a solitary arterial trunk giving rise to a single coronary artery and branch pulmonary arteries and in which there was absence of the ascending aorta with the totality of the neck vessels arising from the descending aorta. Either a fifth or a distal sixth aortic arch could have provided the connection between the solitary arterial trunk and the descending aorta depending on the level of regression of the ventral aorta. Further confusion exists taking into account that a persistent fifth arch is nearly indistinguishable from a patent ductus arteriosus, with half the expected number of smooth muscle cell layers in the media as documented by Silver and colleagues.[54] Moreover, Freedom *et al.*[43] reported that focal fibrin deposit and hemorrhage extending from the lumen to the media, may be present in a fifth aortic arch resembling an arterial duct that fails to close or reopens after initial closure. Finally, response of a persistent fifth aortic arch to prostaglandin has been observed clinically.[25,43]

Outcome

The management and outcome of a persistent fifth aortic arch depends on the associated cardiac lesions and the other organs affected. There has been an asymptomatic man in whom the diagnosis of a persistent fifth aortic arch associated to a secundum atrial septal defect was made at the age of 31 years.[19] It is important to realize the potential hemodynamic value of a persistent fifth aortic arch. In cases with systemic to systemic arterial connection where frequently coarctation of aorta or interrupted aortic arch are associated, the existence of an alternative source of blood supply is clearly advantageous. Furthermore, in cases with systemic to pulmonary or pulmonary to systemic connections (e.g. pulmonary atresia or aortic atresia and interrupted aortic arch respectively) its existence is crucial. Among the treatment strategies performed for this condition, successful balloon dilation of either coarctation or recoarctation of a persistent fifth aortic arch[21,29,33,56] giving a systemic to systemic arterial connection has been reported. A variety of surgical techniques to repair a double-lumen aortic arch associated with coarctation of aorta or interrupted aortic arch[27,29,30,34,55,56,56A] and pulmonary artery as first branch arising from the ascending aorta[14,47] have been described.

Superoinferior Ventricles and Hearts with Twisted Atrioventricular Connections

Hearts with a superoinferior ventricle relationship, many with a crossed or more appropriately twisted atrioventricular connection are unusual forms of congenital heart malformations (Figs 41E-1, 41E-2).[1–38] These hearts are characterized in part by an unusual spatial relationship between the two ventricles.[3,6,10,13,22,23,38] Indeed, the topography of the ventricular mass relative to the interventricular septum may depart from normal in a number of conditions. The most readily appreciated situations for this departure are observed in patients with dextrocardia with and without situs inversus and/or atrioventricular discordance.[10,22,23,38] In hearts with atrioventricular discordance, the ventricular mass is often aligned about a ventricular septum occupying a more vertical disposition than normal.[39,40] In other patients the ventricular mass may be oriented about a horizontal ventricular septum, thus defining a superoinferior spatial relationship.[1–38] In the setting of this post-cardiac looping rotational anomaly, the superiorly-positioned ventricle is almost always the morphologically right ventricle and the inferiorly-positioned ventricle the morphologically left ventricle.[1–38,41] The majority of hearts with twisted atrioventricular connections are biventricular, but a few examples of twisted atrioventricular connections in hearts with a double-inlet univentricular atrioventricular connection have been described.[21,42,42A] These hearts include those with a double inlet left or right ventricle. A superoinferior ventricle spatial relationship does not lend itself readily to the prediction of the type of atrioventricular connection.[43–46] Not infrequently despite a concordant atrioventricular connection, the great arteries are levo-positioned relative to one another when the ventricles have a superoinferior ventricular relationship.[10,13,14,22,23,32,38,47–50] In most hearts with a biventricular atrioventricular connection, the atrial and ventricular inlet septa are aligned in a single plane, and the two blood streams from the atria down to the ventricular apices are parallel as seen in the four chamber cross-sectional echocardiogram and angiocardiogram. Some hearts, however, have a varying degree of atrial septal malalignment with a loss of normal parallel connection axes.[38,42,51–54] Externally, these hearts are characterized by an unexpected spatial relationship of the cardiac chambers and great arteries for the given segmental connection. Internally, the blood flow tracts from the atria down to the ventricular apices spiral around each other, and the atrial and ventricular septa show an angulated or curved configuration.[38,42,51–54] Thus the heart appears twisted along its base-to-apex axis (Fig. 41E-1); the spatial orientation of the cardiac chambers and great arteries being governed by the degree of twisting and also by the presence of the frequently found ventricular hypoplasia. In those hearts with a greater degree of twisting, each atrium is connected to the contralateral ventricle, and the two atrioventricular blood streams "criss-cross," actually spiralling almost 180º to each other. Frequently, the ventricles are arranged in a superoinferior or "upstairs-downstairs" fashion, and the ventricular septum tends to be horizontal. The twisting occurs in either a clockwise or counter-clockwise direction. Usually the heart with the ventricular mass exhibiting a right-hand pattern (d-ventricular loop) is twisted in a clockwise direction, while the heart with a ventricular mass of an l-loop configuration is twisted in a counter-clockwise direction. The common directions of twisting place the right ventricular inlet superior and anterior to the inlet of the morphologically left ventricle. Very rarely, the heart appears twisted in a direction opposite to that seen in most hearts with a twisted atrioventricular connection with the right ventricular inlet inferior and posterior to the left ventricular inlet.[38,42,51–54] Thus in some patients with superoinferior ventricles, the atrioventricular connections are crossed, rather than parallel.[12,27–45] Anderson revisiting his earlier concept of the criss-cross heart defined the essence of crossed atrioventricular connections as a rotational abnormality of the ventricular mass so that the relationships of the ventricular chambers are not as anticipated for the given atrioventricular connection.[21] Furthermore he asked "Is a criss-cross an abnormal relation or connection?" It is an abnormal relationship for the type of atrioventricular connection. Stated in another way: one usually anticipates in situs solitus with a concordant atrioventricular connection, a harmonious ventricular relationship and pattern of internal organization: that is a right-sided morphologically right ventricle with a right-hand type of internal organization (so-called ventricular d-loop). But in some hearts with atrial situs solitus, atrioventricular concordance and crossed atrioventricular connections, the type of atrioventricular connection and ventricular relationship are not harmonious: i.e. in a concordant atrioventricular connection, but with crossed atrioventricular connections, the morphologically right ventricle might be leftward and superior with a left-hand pattern of internal organization.[38,55–58] Thus the lesson one learns from those hearts where the atrioventricular connection is not predictive of the ventricular relationship is that one must state both the type of atrioventricular connection and the type of ventricular relationship or situs.

On examination of those hearts with crossing atrioventricular connections, Seo and his colleagues point out those unifying features: a superior and anterior location of the tricuspid valve in the setting of rotational malalignment between the atrial and ventricular septal structures.[28] This malalignment may be lateral, or rotational, or a combination of both.[59] Ando and his

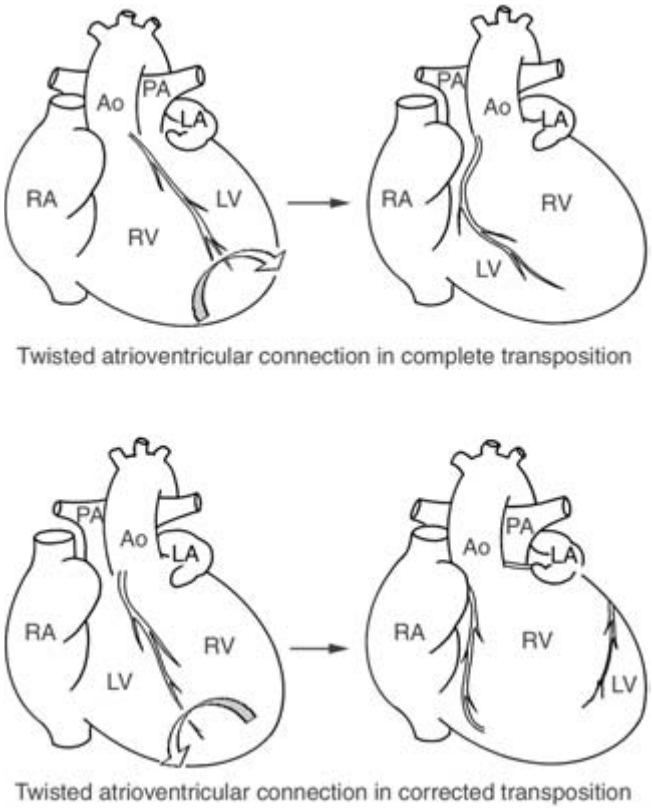

Fig. 41E-1 Twisted atrioventricular connections. When there is concordant atrioventricular connection as in upper panel, twisting is usually in a clockwise direction. When there is discordant atrioventricular connection, twisting is usually in a counter-clockwise direction. Lesser degree of twisting results in superoinferior relationship of the ventricles with the right ventricle being the upper chamber. Greater degree of twisting may result in side-by-side ventricles with complete crossing blood flow at the atrioventricular junction. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

colleagues had previously designated the malalignment as parallel or crossed.[41] Seo also takes issue with the designation criss-cross atrioventricular connection, suggesting that this is not entirely accurate as it is the ventricular inlet tracts that are crossed. He and his colleagues are persuaded that twisted atrioventricular connection, rather than crossed, is a more appropriate designation.[28,51] Using this designation, the two atrial outflows cross at the atrioventricular level. Hearts with most peculiar abnormalities of the base–apex axis, characterized by us as so-called "topsy-turvey" hearts may also have superoinferior ventricles.[38] In this extremely peculiar malposition, the base–apex axis is abnormally rotated by nearly + 180 degrees.

Associated cardiac anomalies in hearts with twisted atrioventricular connection

We have discussed in detail elsewhere those cardiac anomalies commonly found in hearts with twisted atrioventricular connections and superoinferior ventricles.[38] Suffice it to say, the majority of hearts with twisted atrioventricular connections and superoinferior ventricles have an associated ventricular septal defect, pulmonary or less commonly systemic outflow tract obstruction (including aortic atresia), and many have some degree of ventricular hypoplasia, usually affecting the morphologically right ventricle. Abnormalities of ventriculoarterial connection are particularly common with many patients demonstrating a discordant or double-outlet ventriculoarterial connection.[1–37] The atrioventricular junction is frequently abnormal as well with overriding and straddling tricuspid valves and in some patients annular hypoplasia.[1–37] Left juxtaposition of the atrial appendage has been observed in these patients as well.[10,38] In a recent report of 36 patients with atrioventricular discor-

dance, one patient whose ventriculoarterial connection was double-outlet right ventricle also had crossed atrioventricular connections.[60] A number of these patients have been found to have pre-excitation.[8,27] It is uncommon for the ventricular septum to be intact.[27,29,34] Some patients with superoinferior ventricles and discordant atrioventricular connections have concordant ventriculoarterial connections, so-called isolated atrioventricular discordance, thus making them candidates for atrial repair of the Mustard or Senning type (see also Chapter 26B). Patients with twisted atrioventricular connections and superoinferior ventricles may be candidates for a biventricular repair of various types while others for univentricular palliation.[61–66] It is the important ventricular hypoplasia of the systemic ventricle, straddling atrioventricular valve, intermingling of chordae and papillary muscles that necessitates univentricular palliation.

There is a substantial literature describing the pathological features of these hearts, and their echocardiographic, MR-imaging, and angiographic features.[10,13,14,22,23,32,38,42,51–54,67–76] Fetal diagnosis has been recorded as well.[52,68] Magnetic resonance imaging seems the superior non-invasive imaging modality for the diagnosis of twisted atrioventricular connections.[42,54,75,76]

Surgical procedures

From our experience and that in the literature, patients with superoinferior ventricles and twisted atrioventricular connections can benefit from a variety of surgical procedures.[61–66,77] In general, these can be divided into biventricular repairs and univentricular repairs (Table 41E-1).

From January 1979 to May 2002 at the Toronto Hospital for Sick Children, we assessed 31 children (18 males, 13 boys) with superoinferior ventricles ± twisted atrioventricular connections. Levocardia was noted in 24/31, dextrocardia in 6/31, and mesocardia in 1/31. The situs was solitus in 28/31 inversus in 1/31 and situs ambiguus in 2/31. The basic types of heart could be catalogued as follows:

Table 41E-1 Types of repair for hearts with superoinferior ventricles and twisted atrioventricular connections

Biventricular repair
VSD* closure with/without repair of POTO
Mustard or Senning repair
Arterial switch
Double switch
Univentricular palliation

POTO, pulmonary outflow tract obstruction; VSD, ventricular septal defect.

1 AV–VA concordance: 4/31
2 AV concordance-VA discordance: 8/31
3 AV–VA discordance: 4/31
4 AV discordance-VA concordance (isolated atrioventricular discordance): 2/31
5 AV concordance with DORV: 11/31
6 Topsy-turvy: 2/31 (both with AV–VA concordance and A–P windows).

The atrioventricular junction was abnormal in 21/31 and normal in 10/31.

The aortic arch was left-sided in 27/31, and the aortic arch was right-sided in 4/31. For the group as a whole, univentricular palliation was planned or completed in 23/31 and biventricular repair in 7/31 including two Mustard repairs in the patients with isolated atrioventricular discordance (see Chapter 26B). Heart transplantation was contemplated in 1/31 (diagnosed and listed *in utero*). Fifteen of the 31 patients have died, most in the first decade of the experience, including both of the patients with so-called topsy-turvey hearts.[23,38] The mortality rate was significantly higher in patients undergoing biventricular-type of repair compared with patients having univentricular-type of repair (71% and 43%, respectively). Among the 15 patients with univentricular-type of repair who died, 66% occurred before the completion of the Fontan procedure.

Kartagener's Syndrome

Kartagener first described the clinical triad of dextrocardia with situs inversus totalis, sinusitis, and bronchiectasis (Fig. 41F-1).[1,2] In the first English language report, Adams and Churchill found that 21.7% of patients with situs inversus had bronchiectasis, indicating that this association was not fortuitous.[3] The respiratory difficulties, including recurrent middle ear infections in this syndrome, result from hypomotility or immotility of the tracheobronchial cilia.[3–18] The basic defect is lack of ciliary dynein.[3–18] Males with this disorder are usually infertile, and absence of dynein in the sperm tails accounts for spermatic immotility.[3–19]

Prevalence and genetics

Primary ciliary dyskinesia or immotile cilia syndrome is an autosomal recessive disorder affecting ciliary movement with an incidence of 1 in 20 000–30 000.[3,6,7,10,14–21] Dysmotility to complete immotility of cilia results in a multisystem disease of variable severity with recurrent respiratory tract infections leading to bronchiectasis and male subfertility. Ultrastructural defects are present in ciliated mucosa and spermatozoa. Kartagener syndrome with situs inversus is found in about half of the patients with primary ciliary dyskinesia or immotile cilia syndrome.[3–19] The syndrome has been diagnosed in twins.[22] Guichard and colleagues have found that Kartagener syndrome is a heterogeneous condition that may be associated to axonemal dynein intermediate chain gene mutations.[21,21A]

Outcome analysis

The triad of Kartagener's syndrome has been established in the neonate and as well in a 75-year-old adult.[23–25] "Man's best friend" is not immune from this disorder as Kartagener's syndrome has also been documented in the Dachshund dog.[26] This disorder is most frequently established in childhood, frequently in the investigation of the child or adolescent with recurrent respiratory infections, or in the pediatric patient with recurrent sinusitis and nasal polyps and discharge.[27] It is often in the clinical setting of the investigation for recurrent respiratory infections that frontal chest radiography demonstrates the cardiac malposition.[27] While it is uncommon to establish this diagnosis in the neonate, in at least one neonate the diagnosis of primary ciliary dyskinesia was confirmed by both ultrastructural and functional investigations.[23] The immotile cilia syndrome was suspected in this patient because of respiratory distress, situs inversus, abnormal nasal discharge and a radiograph showing a hyperinflated chest. Others have also made this diagnosis in the neonate and young infant.[24] As pointed out by Peroff, sinusitis varies from mild to severe with nasal polyposis and there may be hypoplasia or agenesis of the sinuses.[27] Similarly, symptoms of bronchiectasis range from mild to very severe.[27] Lobectomy has been required because of massive hemoptysis.[28] Bronchiolitis may dominate the clinical picture in some older patients.[29] Some patients with Kartagener's syndrome have also had rheumatoid arthritis, but it is unclear whether this is just a chance association.[30] When the diagnosis of immotile ciliary syndrome is established early in childhood, vigorous attention

to "pulmonary toilet" significantly reduces the incidence of bronchiectasis.[27] Rarely, as in the patient reported by Gomez de Terreros Caro and colleagues, the diagnosis of Kartagener syndrome is made in the eighth decade of life.[25]

Congenital heart disease can occur in the patient with Kartagener's syndrome, and one tends to assign symptoms to the congenital heart malformation, and ciliary dysfunction may be overlooked.[27,31–35] It has been stated that cardiac defects occur in about one tenth of affected individuals.[31] Congenitally corrected transposition of the great arteries, ventricular septal defect, tetralogy of Fallot and complex forms of univentricular atrioventricular connection have been identified in patients with Kartagener's syndrome.[32–35] Polysplenia and incomplete lateralization of the abdominal viscera have also been seen in these patients.[36,37] Patients with important congenital heart disease have undergone successful cardiac and noncardiac surgery.[38] In the older patient with Kartagener's syndrome, end-stage bronchiectasis has been treated by heart–lung or double-lung transplantation.[39–41]

Myocardial Noncompaction

Noncompaction of the ventricular myocardium is a rare congenital abnormality characterized by the presence of numerous, excessive prominent trabeculations and deep intertrabecular recesses which communicate with the left ventricular cavity (Fig. 41G-1).[1–5] This particular form of cardiac muscle disease has not yet been classified as a separate and distinct entity by the World Health Organization, but rather it has been categorized as an unclassified cardiomyopathy.[6] Isolated noncompaction of the ventricular myocardium clearly departs in its morphology from typical hypertrophic (see Chapter 21), dilated (see Chapter 46) and restrictive cardiomyopathies.[7] The disease uniformly affects the left ventricle, and less commonly the right ventricle. Myocardial noncompaction has also been called "spongy myocardium," persistent myocardial sinusoids, myocardial dysgenesis, etc.[8–11] While in the past we had used the designation of "spongy myocardium,"[12,13] we acknowledge, as do others, that myocardial noncompaction better characterizes the basic nature of this disorder.[3] Noncompaction of the ventricular myocardium is believed to be a disorder of arrested endomyocardial embryogenesis.[1–5,7] Ventricular noncompaction may occur as a primary disorder, and it is being recognized with increasing frequency.[4,14–18] It is also well known to accompany a variety of congenital cardiac disorders. These include critical aortic stenosis usually of the neonate; pulmonary atresia and intact ventricular septum; some forms of "single" ventricle pathology; anomalous left coronary artery, and the rare variant of an imperforate tricuspid valve or tricuspid stenosis with a congenitally absent pulmonary valve.[12,13,19–31] This latter association has been extensively reviewed by Litovsky and colleagues[31] with most of the reported cases dating from the publication of Marin-Garcia and colleagues three decades ago (see also Chapter 30).[19] Interestingly, left ventricular hypertrabeculation/noncompaction has a peculiar association with neuromuscular abnormalities.[31A] This chapter will concern itself only with the primary form of noncompaction of the left ventricular myocardium.

Incidence and genetics

In a recently published study of the epidemiology of childhood cardiomyopathy in Australia, Nugent and colleagues found an annual incidence of primary cardiomyopathy of 1.24 per 100 000 children less than 10 years of age.[31A] This compares to the 1.13 per 100 000 documented by Lipshultz and colleagues in two regions of the USA.[31B] The Nugent study identified left ventricular noncompaction in 9.2% of their cases. In an echocardiographic study published by Ritter and colleagues some years ago, the frequency of isolated left ventricular myocardial noncompaction was 0.045% in an adult population.[15] Strauss and Lock have provided an interesting editorial to the papers of Nugent and Lipshultz and their respective colleagues.[31C] While left ventricular myocardial noncompaction occurs as a sporadic event, there are a number of reported cases with a familial pattern and a number of cases with typical dysmorphic features and/or chromosomal abnormalities have been recorded.[1,3,4,5,7,14,15–18,32–39] Bleyl and colleagues presented a family with myocardial noncompaction in which 6 affected individuals demonstrated X-linked recessive inheritance of this trait.[37] Affected relatives presented postnatally with left ventricular failure and arrhythmias, In this kindred, genetic linkage analysis localized isolated left ventricular myocardial noncompaction to the Xq28 region in the G4.5 gene, where other myopathies with cardiac involvement have been located. Pauli and colleagues described a dysmorphic 7-year-old girl and complex heart disease including ventricular myocardial non-compaction. She was found to have a distal 5q deletion. Fluorescent *in situ* hybridization showed that this deletion included the locus for the cardiac specific homeobox gene, CSX suggesting that some instances of ventricular myocardial noncompaction may be caused by haploinsufficiency of CSX.[38] Ichida and colleagues mentioned two large families with a high incidence of the disease, suggesting autosomal dominant inheritance.[33] Clearly there appears to be considerable genetic heterogeneity amongst patients with isolated left ventricular myocardial noncompaction.[32] One patient in this survey was noted to have a father with hypertrophic cardiomyopathy, and another patient's brother had a restrictive cardiomyopathy without features of noncompaction.[14] Isolated left ventricular myocardial noncompaction has been identified in the patient with Roifman's syndrome, Noonan's syndrome, Barth syndrome and Melnick-Needles syndrome, amongst others.[3,11,14,16,17,39A,40] The dysmorphic facial appearance commented on by some including Chin and colleagues include a prominent forehead, bilateral strabismus, low-set ears, and micrognathia.[3]

Morphology of isolated left ventricular myocardial noncompaction

During the early stages of intrauterine cardiac development, the loose trabecular network of the sponge-like myocardium undergoes compaction with resolution of the large intertrabecular spaces.[41–43] Formation of a wide inner spongy layer representing the primitive endocardium invaginates into the cardiac jelly. With progression of this process, the outer myocardium

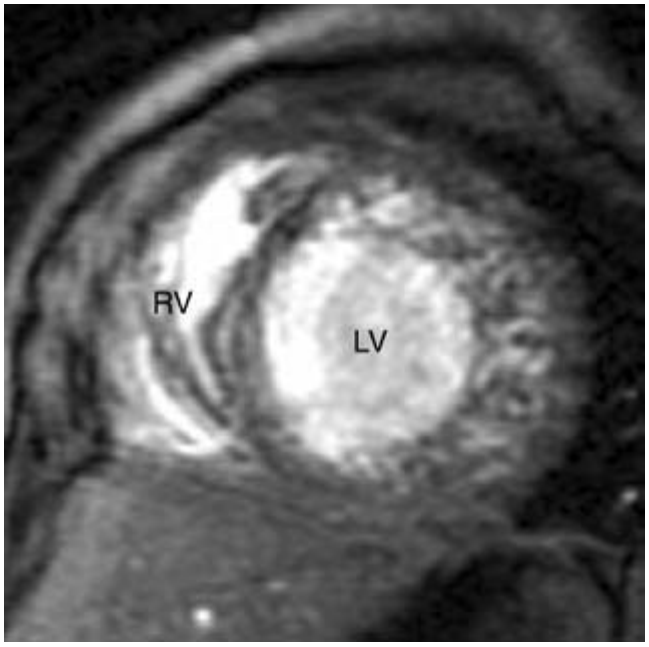

Fig. 41G-1 Myocardial noncompaction. Cine MR image of the ventricles in short axis shows tiny tracks between the fine trabeculations in the thickened myocardium of the free wall of the left ventricle (LV). RV, right ventricle.

becomes compact whereas the inner component differentiates into trabeculae carnae, papillary muscles and chordae tendineae.[41–43] It has been suggested elsewhere that an arrest in this process of normal myocardial development results in noncompaction of the ventricular myocardium,[1–5,7,14–18] a pattern of myocardium normally observed in non-mammalian vertebrates including fish, amphibians and reptiles.[41–43] Histological examination confirms that the so-called spongy appearance of the noncompacted left ventricular myocardium is due to the deep intertrabecular recesses lined by endothelium which extend close to the epicardial surface[3,14–18] (Fig. 41G-2). Increased fibrous and elastic tissue of the endocardium is common, perhaps reflecting as suggested by Chin *et al.* some degree of subendocardial ischemia.[3]

Outcome analysis

There are only a few cases recorded of fetal diagnosis of isolated left ventricular myocardial non-compaction.[44,44A,45] Kohl and colleagues reported a 5-year-old-girl with this condition in whom in retrospect the diagnosis could be made on the fetal study performed at 23 weeks' gestation.[44] More recently Moura and colleagues reported 4 cases of isolated noncompaction recognized in the fetus, 2 of which were familial and 2 sporadic.[45] Three fetuses died and 1 survived.

The diagnosis of isolated left ventricular myocardial noncompaction has evolved from one once only established at the autopsy table to clinical diagnosis based on typical echocardiographic features, MRI imaging and CT findings.[3,4,14–18,33–39,46–54] The diagnosis of isolated left ventricular myocardial noncompaction usually conveys a poor prognosis with clinical features dominated by pump failure, malignant ventricular dysrhythmias, and systemic embolism.[3–5,17,18,33,34,36–39,47–49,55] This latter clinical feature reflects both on the basic morphological features of the disorder which likely predispose to mural thrombi and the reality of progressive deterioration in ventricular function. Sudden death has also been reported.[3,50] A number of catheter studies reveal restrictive physiology with a normal end-diastolic volume, but increased left ventricular filling pressures.[3,4,14,16] There is increasing awareness of this disorder and the echocardiographic features are now fairly well entrenched in the literature.[4] From the increasing number of clinical reports it has become evident that in some patients with isolated left ventricular myocardial noncompaction the clinical course may be more indolent.[4,14–16] This is quite apparent from the nationwide survey conducted by the Japanese and published in 1999.[14] This survey identified 27 patients, with their ages at presentation ranging from 1 week to 15 years (median, 5 years) with the follow-up lasting as long as 17 years, median 6 years. Sixteen of

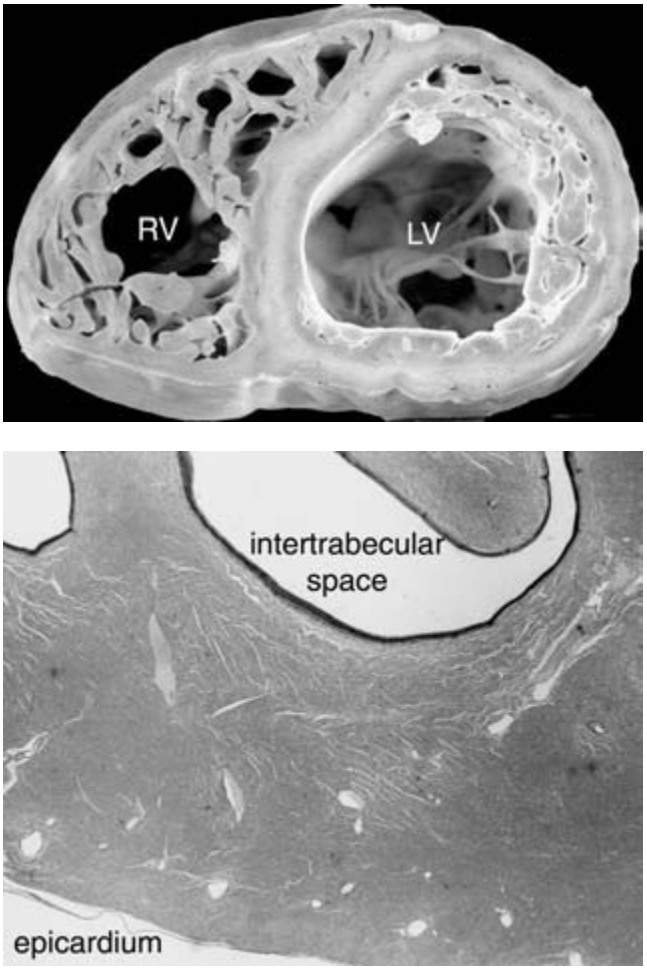

Fig. 41G-2 Explanted native heart from a 3-year-old female with isolated myocardial noncompaction. **A**. Clefts of intertrabecular space in the inner myocardium of the free wall of the left ventricle (LV). Low power photomicrograph (Movat pentachrome stain) of left ventricular myocardium shows the large, deep intertrabecular spaces within the inner portion of the left ventricular free wall. The subepicardial layer shows normal myocardium with intramural coronary arteries and veins. The intertrabecular spaces are lined by endocardial fibroelastosis. RV, right ventricle.

these patients demonstrated gradually depressed systolic function on echocardiography and 6 showed Doppler evidence of impaired diastolic function. Most of these patients according to the authors have shown no cardiovascular symptoms and have as yet not required medications.[14] While 2 patients died during the follow-up period and 1 patient is a candidate for a heart transplant, the prognosis in this group of patients is certainly better than that reported by Chin *et al.*,[3] acknowledging that the patients in the report of Ichida were identified from a questionnaire sent to 150 hospitals where a pediatric cardiology division exists.[14] Similar to the experience reported by Ichida,[14] the patients reported by Ritter and his colleagues seemingly had a more benign course as well.[15] Reynen *et al.* published the case of a 35-year-old man noted by left ventricular angiocardiography to have isolated left ventricular myocardial noncompaction at 15 years of age remaining asymptomatic until 35 years of age, at which time he presented in florid heart failure.[56] Interestingly, this patient had undergone closure of a secundum atrial septal defect at 6 years of age based on oximetry data. Nine years later because of a heart murmur, left ventricular angiography was performed establishing the diagnosis of noncompaction.[56]

Any number of electrocardiographic abnormalities have been described in patients with isolated left ventricular myocardial noncompaction including diffuse ST–T wave changes, sinus node dysfunction, complete left bundle branch block, Wolff–Parkinson–White syndrome, malignant ventricular arrhythmias, sudden death and complete heart block, amongst others.[3–5,14–18,34,39,47–49,57,58] Left bundle branch block is certainly uncommon in the unoperated pediatric population. In the patient presenting with features of heart failure and cardiomyopathy, one should certainly want to exclude isolated left ventricular myocardial noncompaction. The etiology of myocardial ischemia in these patients is unclear. While the gross coronary circulation has usually been characterized as normal in autopsied specimens, Chin and his colleagues wondered whether intramural perfusion could be adversely affected by the prominent trabeculations and deep intertrabecular recesses.[3] Positron emission tomography was used by Junga and colleagues to evaluate the presence or absence of myocardial ischemia.[59] They found that children with isolated left ventricular myocardial noncompaction had restricted myocardial perfusion and decreased flow reserve in the areas of noncompaction.[59] They wondered whether these perfusion defects in noncompacted areas could be contributory to the myocardial dysfunction and to the genesis of the arrhythmias. Jenni and his colleagues who have had an extensive experience with isolated left ventricular myocardial noncompaction have also documented coronary microcirculatory dysfunction in these patients using positron emission tomography and ^{13}N-ammonia,[60] as has Soler and coworkers using MRI to demonstrate left ventricular subendocardial perfusion deficits.[61A]

A total of 14 cases of left ventricular ventricular noncompaction were seen at the Hospital for Sick Children between September 1988 and January 2001. The male to female gender ratio was 1.33 : 1. The average age at presentation was 3.9 years with a range between 1 day and 14 years of age. This series focused on isolated ventricular noncompaction. It did not exclude minor valvular lesions (such as valvular regurgitation or Ebsteinoid anomalies of the tricuspid valve) or hemodynamically insignificant apical ventricular septal defects. The majority of patients presented with symptoms of congestive heart failure (9/14), 2 patients presented with arrhythmia (WPW and ventricular tachycardia) and no patients presented with thrombotic or embolic events. One patient diagnosed after a screening ECG, ordered because of a strong family history of sudden infant death syndrome and cardiomyopathy, revealed T wave abnormalities. The remaining two cases were diagnosed due to neonatal cyanosis and a neonatal murmur, respectively. Chromosomal abnormalities or syndromal findings were present in at least seven of the patients. These included 2 patients with Barth syndrome, 1 patient with centronuclear myopathy, 1 patient with chromosome 1 deletion and Leber's congenital amaurosis, 1 patient with Roifman syndrome and 2 patients suspected to have "syndromes not yet diagnosed." Half of all males (and no females) had a family history positive for congenital heart disease. Of the 14 patients reviewed, 4 patients progressed to end-stage heart failure and were offered heart transplant. One patient refused transplant and is currently receiving palliative care; he is 3 years of age and has restrictive physiology. Another 22-year-old patient is currently listed for transplant. Two patients received heart transplantation at ages 3 and 11 years, respectively. The latter died suddenly at age 15 due to coronary artery disease. There were no other deaths in our series. Of the remaining 10 patients, 9 patients have evidence of systolic dysfunction and 7 have systolic and diastolic dysfunction on the most recent echocardiogram performed in our hospital. With the exception of 1 patient who was lost to follow-up, all patients have had clinical evaluation within the past year. Over 90% of the patients currently being followed with ventricular noncompaction require anti-failure with or without arrhythmic medical therapy.

Can the course of the disease be modified by therapy? There is little information about this and it is uncertain whether one can make assumptions based on the documented courses and outcomes of patients with a classically dilated or restrictive cardiomyopathy.[4–18,61] Toyono and colleagues have reported the case of a 4-month-old infant with isolated left ventricular noncompaction who was treated with carvedilol.[61] Hemodynamic studies and various types of imaging-including echocardiography, radiographic angiography, magnetic resonance imaging, and single photon emission computed tomography with ^{201}Tl, ^{123}I-beta-methyliodophenylpentadecanoic acid (BMIPP), and ^{123}I-metaiodobenzylguanidine (MIBG) were performed before and 14 months after treatment. In this patient, left ventricular ejection fraction increased from 30% to 57%, and left ventricular end-diastolic volume, end-systolic volume, and end-diastolic pressure showed striking reductions during treatment. Left ventricular mass decreased to about two thirds of the baseline value after treatment. Per cent wall thickening increased after carvedilol in the segments corresponding to noncompacted myocardium. A mismatch between ^{201}Tl and BMIPP uptake in the area of noncompaction observed before carvedilol disappeared after treatment. Impaired sympathetic neuronal function shown by MIBG recovered after treatment. Thus in this single patient carvedilol had beneficial effects on left ventricular function, hypertrophy, and both metabolic and adrenergic abnormalities in isolated left ventricular noncompaction. Thus one would wonder that when a patient is identified in the asymptomatic phase of the disorder, whether they should be anticoagulated, at least using salicylates. Also, whether these patients should be placed on beta blockers, ACE inhibitors, etc., is uncertain, but since most if not all patients with this disorder will eventually deteriorate to the point of requiring

cardiac transplantation,[62,63] these maneuvers may prove beneficial. Finally, there is increasing recognition of isolated myocardial noncompaction, raising the question of rarity or missed diagnosis.[64,65]

In summary, isolated left ventricular myocardial noncompaction is a rare disorder with considerable genetic heterogeneity. This disease may occur as a sporadic event or in a sex-linked pattern of genetic inheritance. It can also be found in females. The clinical course is characterized by ventricular dysfunction, serious cardiac rhythm disturbances and systemic emboli. In some patients it seems the clinical course is fulminant, rapidly concluding in death or the need for a cardiac transplant. In other patients, the clinical course may be quite protracted. The etiology of isolated left ventricular myocardial noncompaction is unknown. Whether the course of the disease when detected in asymptomatic patients can be moderated by afterload reduction, etc., is unknown. Because of the basic morphological features of isolated left ventricular myocardial noncompaction, we would suggest early anticoagulation to prevent mural thrombi and systemic emboli.

Systemic Venous Anomalies Including Divided Right Atrium

Many anomalies of systemic venous anatomy have been observed in patients with or without congenital heart disease.[1] Most of these do not have important clinical implications, but are merely anatomical variations. These include the retroaortic innominate vein among many other variations of systemic venous anatomy.[2–7] Other systemic venous anomalies may be intrinsic components of specific congenital heart malformations, i.e. azygos continuation of the inferior vena cava in patients with left isomerism/polysplenia (see Chapter 34). Yet other systemic venous malformations may be unmasked and recognized only after completion of cardiac surgery.[8–18] These include hepatic vein connection to the coronary sinus or left or pulmonary venous atrium which if not appreciated and dealt with at the time of total cavopulmonary connection will result in postoperative right-to-left shunting and hepatic veno-venous shunting (see Chapter 37), etc. This chapter will consider the following anomalies (Table 41H-1).

Right superior vena cava to left atrium

Right superior vena cava to left atrium (Fig. 41H-1) is one of the rare causes of cyanosis and has been recognized in both the pediatric as well as in the adult patient.[1,19–29] This condition was likely first reported in the English literature by Wood in 1957,[19] and up to 1995, Alday and colleagues identified from the literature at least 15 additional cases.[23] When this occurs in isolation, the development of cyanosis is usually insidious. This disorder may also be responsible for recurring intracerebral abscesses.[26] The diagnosis can be made from contrast echocardiography or from radionuclide imaging.[25] Surgical diversion of the anomalously connected right superior vena cava to the right atrium has been achieved using any of a variety of techniques.[20,30–32] In some patients the right superior vena cava drains into both atria (Fig. 41H-1B).[33] This condition may be a component of total anomalous systemic venous connection, an extremely rare finding (Fig. 41H-1C).[1,19,34–37] Surgical repair of this last condition has been achieved as well.[34–37]

Absent right superior vena cava

Absence of the right superior vena cava is an uncommon condition in the patient with normally lateralized atria.[38–47] In this situation, usually the right superior vena cava is either completely absent or represented by a vestigial fibrous cord (Fig. 41H-2A,B). Drainage of systemic venous blood from the head and neck is usually via the left brachiocephalic vein to the left superior vena cava, coronary sinus and right atrium, or to the left atrium if the coronary sinus is unroofed.[43–46] Lenox and her colleagues identified this malformation in two of 1550 postmortem heart specimens with congenital heart disease,[41] and the Boston Children's Cardiac Registry encountered this condition in 3 of 3226 specimens with congenital heart disease.[43] Among patients with normal situs, Bartram and colleagues found that slightly > 50% had no other form of congenital heart disease.[43] Interestingly, the survey by Bartram found a male : female ratio of 2.3 : 1.[43] One of the more significant features of this condition is that the sinoatrial node is often poorly formed and patients, usually adults, may develop "sick sinus syndrome" requiring pacemaker therapy.[40,43,45,47] Bartram and colleagues list a further six issues that make this diagnosis important (Table 41H-2).[43]

Rarely as in the case reported by Saunders and colleagues, both superior vena cavae are absent.[48] In this patient, blood from the arms, head, and upper torso returned to the right atrium through the azygos vein and the inferior vena cava, mimicking chronic superior vena cava obstruction.

Unroofed coronary sinus

The coronary sinus may be partially or completely unroofed, and in this situation in an otherwise normal heart this defect results in a left-to-right shunt (Fig. 41H-3A,B).[49–68] All-too-commonly, the effect of coronary sinus unroofing is masked by associated congenital cardiac malformations. Raghib and his colleagues were perhaps the earliest to describe the constellation of anomalies now bearing his name (Fig. 41H-3C).[69] These included termination of left superior vena cava in left atrium, atrial septal defect, and absence of coronary sinus. In some patients an unroofed coronary sinus provides an alternative pathway to pulmonary or systemic venous flow in the presence of obstructive lesions in the left or right atrioventricular junction, respectively.[51,62] An unroofed coronary sinus can be easily repaired by patching the defect.[30] In many patients with an unroofed coronary sinus, a left superior vena cava connects directly with the left atrium.[1,19,50–53,56,69] This condition, when isolated, can be treated either surgically or by intervention (Fig. 41H-4).

Left superior vena cava draining to the left atrium

A left superior vena cava connecting directly to the left atrium (Fig. 41H-5) promotes a right-to-left shunt.[1,19,19A,50–53,56,69–82] When the coronary sinus is normally formed and not unroofed, several procedures have been used to treat this condition. These

include an intra-atrial baffle; anastomosis of the left superior vena cava to the right superior cava or right atrial appendage; simple ligation; or construction of a left cavopulmonary connection. When the left brachiocephalic vein is of reasonable calibre, the left superior vena cava can be safely ligated with the knowledge that there is not coronary sinus atresia, or this venous channel can be occluded in the catheter laboratory with any of a variety of catheter-delivered devices.[1,19,19A,50–53,56,69–80] In the patient with a small left brachiocephalic vein, this vein can be patch-graft enlarged and then the left superior vena cava can then be ligated.[54] Others, even in the absence of a left brachiocephalic vein, have ligated the left superior vena cava, measuring carefully venous pressure above the level of ligation, acknowledging that this procedure is not always safe.[19,30,82] Collateralization often allows this maneuver to be safely carried out. In other situations the ostium of the left superior vena cava at its point of termination into the left atrium can be baffled into the right atrium.[30,57,76] Patients with adequately-sized pulmonary arteries and low pulmonary artery pressure and vascular resistance can be treated with a cavopulmonary connection.[66,76,77]

IVC, inferior vena cava; LV, left ventricle; RA, right atrium; RUPV, right upper pulmonary vein; RV, right ventricle.

Coronary sinus ostial atresia/stenosis

Coronary sinus ostial atresia (Fig. 41H-6) is a very uncommon congenital abnormality.[1,52,83–94] One of the earliest reports was published in 1943 by Prows [83] and in 2002 Ohta and colleagues stated that only 40 cases had been reported in the world's literature.[94] In patients with an otherwise normal heart, coronary venous return in the presence of coronary sinus ostial atresia is mediated through thebesian-vein like channels, and thus this anomaly should not produce symptoms. Yet in some patients coronary venous blood returns to the right heart via a persistent left superior vena cava. Ligation of this vein during repair of congenital heart malformations in patients with atresia or severe stenosis of the coronary sinus ostium may prove fatal.[1,82,83,86,93] Repair of coronary ostial atresia has been reported by Ohta and colleagues in a patient who did poorly after a total cavopulmonary connection for the hypoplastic left heart syndrome.[94] The effect of coronary sinus atresia precipitated features of a failing Fontan circulation. The coronary sinus was unroofed into the left atrium and the patient subsequently improved. Tateno and colleagues have also reported repair of atresia of orifice of the coronary sinus.[94A] They reported a 5-year-old girl with a coronary arteriovenous fistula, atresia of the ostium of the coronary sinus and a persistent left superior caval vein all documented by aortography. This patient underwent closure of the fistula and membranous atresia of the coronary sinus ostium. The membrane was excised and the orifice enlarged. Subsequent angiocardiography performed 23 days after the operation showed the reconstructed orifice to be patent, but a second postoperative study at 11 years of age showed acquired closure of the coronary sinus orifice.

While the diagnosis of coronary sinus atresia has usually been made by angiography,[1,85,94] Muster and his colleagues and others have suggested that retrograde flow in the left superior

vena cava as assessed by Doppler echocardiography is suggestive of this condition.[82,90,92]

Hepatic vein connection to coronary sinus or left atrium

In patients with unequivocally lateralized atria, these anomalies are rare.[8–16,95] Hepatic vein connection to coronary sinus (Fig. 41H-7) should not produce symptoms or cyanosis in otherwise normal hearts. However, in patients undergoing a Fontan-type procedure, it is routine to construct the atrial anatomy so that the coronary sinus drains to the lower pressure pulmonary venous atrium. If a hepatic venous connection to the coronary sinus is not recognized pre- or intraoperatively, then postoperatively a right-to-left shunt would become apparent, promoting as well a hepatic veno-venous shunt[96,96A] (see Chapter 37). Similar complications would be anticipated in the patient with a hepatic vein connection to left atrium. Nomura and colleagues

have published the interesting case of a patient who became increasingly cyanosed after the Fontan procedure, initially leading to Fontan takedown to a hemi-Fontan as the etiology of the postoperative hypoxemia was incorrectly attributed to high pulmonary vascular resistance. What was later identified was a wide venous channel connecting the left hepatic vein to the left pulmonary vein which in turn connected to the pulmonary venous atrium. Several years later this unusual vascular channel was successfully ligated when the patient underwent a successful fenestrated Fontan procedure.

Furthermore this complication has been observed in patients with heterotaxia after total cavopulmonary connection when hepatic venous connection to the pulmonary venous atrium was not recognized preoperatively.[17] This complication leads to progressive and severe cyanosis following the Fontan operation and the connection must be interrupted either at surgery or by catheter-based intervention.[17A,17B] The dilated intrahepatic channels as shown by Giamberti and colleagues (fig. 2) suggest persistence of the hepatic venous plexus[96A] (see below).

Persistence of the hepatic venous plexus as the terminal part of the inferior caval vein

Persistence of the hepatic venous plexus (Fig. 41H-8), first recognized by Jolly and his colleagues as a relatively isolated anomaly (with an arterial duct and azygos continuation of the inferior vena cava),[97] this condition is now being recognized with increasing frequency.[98–101] Persistence of the primitive hepatic venous plexus has also been observed in the patient with a hypoplastic but patent hepatic segment of the inferior vena cava as well as in the patient with complex congenital heart disease complicating visceroatrial heterotaxia.[98–101] These connections may promote important arterial hypoxemia after a Kawashima operation, and thus their recognition is important in the preoperative investigation of patients with left iso-

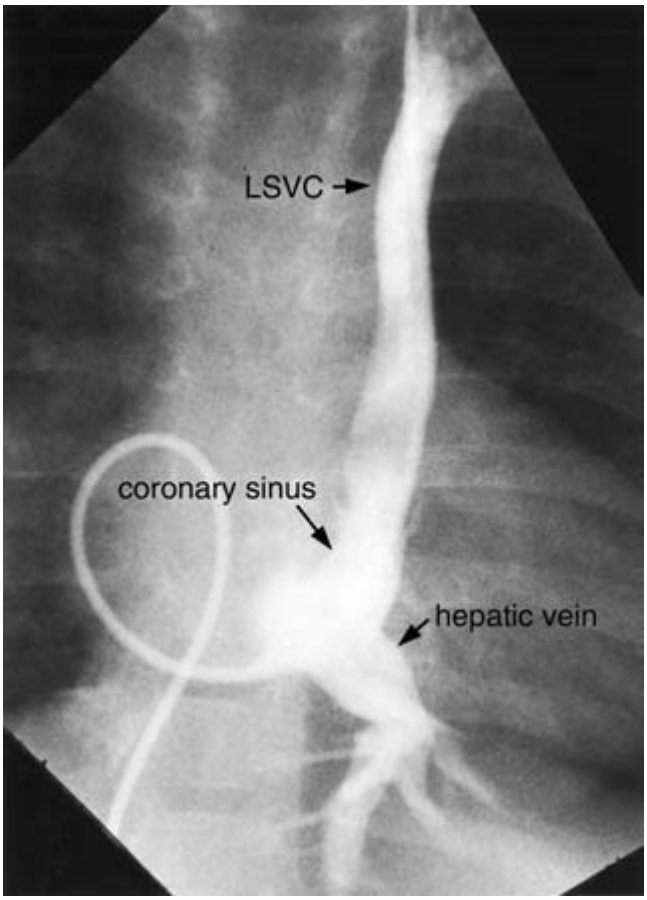

Fig. 41H-7 Anomalous connection of the hepatic vein to the coronary sinus that drains the left superior vena cava (LSVC).

merism/polysplenia[101] (see also Chapter 37). This recognition is facilitated by inferior vena caval angiography performed before palliation with a cavopulmonary shunt or at the catheter study performed before total cavopulmonary bypass.[101] Furthermore, if this condition is not diagnosed preoperatively, its recognition at a postoperative catheter study may lead to the erroneous conclusion that this malformation results as a complication of this surgery.[18,101–104]

Other congenital anomalies of the systemic veins include aneurysmal dilatation of the right or left superior vena cava, hypoplasia of the inferior vena cava, and congenital arteriovenous fistula. We have discussed in detail elsewhere the pathological and morphological features of the persistent venous valve, and its frequent association with hearts characterized by severe right ventricular inflow and outflow tract obstruction.[1,105–119] A divided right atrium can occur in isolation, producing symptoms in the infant or the adult (Fig. 41H-9).[107–120] For symptomatic patients experiencing right heart failure or cyanosis because of right-to-left shunting through a patent foramen ovale or atrial septal defect surgical excision can remedy the situation.[108–113,120] The incomplete regression of the embryonic right valve of the sinus venosus may leave a fenestrated or an unfenestrated membrane in the right atrium that should be considered a normal benign variant of the so-called "Chiari's" network.[105,106,118] This finding was noted in 27 of 1728 transthoracic two-dimensional and Doppler echo-cardiographic studies consecutively performed over a 4-month period.[118] Rarely as in the case published by Inoue and colleagues, a divided right atrium is associated with extensive coronary vein abnormalities.[121] There is also some experience, albeit limited with catheter-based intervention for cor triatriatum dexter.[122] The levoatrial cardinal vein is an uncommon finding, usually, but not invariably identified in patients with mitral atresia and other forms of hypoplastic left heart syndrome connecting the left atrium or left-sided pulmonary vein to the left brachiocephalic vein (Fig. 41H-10).[123–132] Persistence of a levoatrial cardinal vein complicates the completion of a Fontan-type operation, and if not interrupted results in a right-to-left shunt after completion of a total cavopulmonary connection.[133] This vein can be interrupted in the catheter laboratory.[133] Finally, connection of the inferior vena cava to the left atrium is exceedingly rare, if this situation exists at all.[134]

Isolation of the Subclavian, Innominate, or Left Common Carotid Artery

Isolation of the subclavian, innominate or left common carotid arteries is an uncommon congenital anomaly of the aortic arch system (Figs 41I-1, 41I-2). The embryology, clinical manifestations and imaging algorithms useful in the diagnosis of these uncommon vascular conditions have been discussed elsewhere.[1–8] When either the subclavian artery, the innominate artery or the left common carotid artery is connected inappropriately to the pulmonary artery, isolation of the particular vessel occurs as a result of physiological and anatomic closure of the arterial duct. With closure of the arterial duct, the arch vessel involved is then attached to the pulmonary artery by the ligamentum of the duct, and thus isolated from the systemic circulation.

Embryology

Isolation of the right subclavian artery from the right pulmonary artery with a left aortic arch[1–7] requires regression at two levels in Edwards's hypothetical arch system in this anomaly:[1–3,8] one level, the right arch between the right common carotid and subclavian arteries; the other, the right dorsal aortic root distal to the arterial duct (Fig. 41I-1A). No vascular ring exists in this situation. We have reported bilateral arterial ducts in this situation.[9] For the patient with a right aortic arch and isolation of the left subclavian artery, the left subclavian artery no longer arises from the aorta, but is connected to the left pulmonary artery via a left arterial duct.[1–3,5,10–17] Embryologically there is a regression at two levels in Edwards's hypothetical arch plan:[4] one between the left common carotid and subclavian arteries; and the other, the left dorsal aortic root distal to the left ductus arteriosus (Fig. 41I-1B). Again no ring is formed and cases with bilateral arterial ducts have been reported.[9] Isolation of the right subclavian artery is far less common than isolation of the left subclavian artery.

Isolation of the innominate artery is very uncommon and usually occurs in the setting of a right aortic arch.[18–30] The innominate artery is not connected to the arch.[1–5,18–30] Atresia of the left common carotid and subclavian arteries may also be present. The blood supply to the isolated vessel is via a patent arterial duct or via mediastinal and vertebral pathways. The malformation is the result of interruption of the embryonic arch at two levels: one proximal to the left common carotid artery, the other involves the left dorsal aortic root distal to the left patent ductus arteriosus or ligamentum (Fig. 41I-1C).[3,8,18] The innominate artery is connected to the left pulmonary artery via the left ductus arteriosus or ligamentum. Bilateral arterial ducts have also been described in these patients.[9] Even less common is isolation of the left common carotid artery. Indeed, cases of this anomaly are extremely rare.[31–35] The patients described in the literature exhibited a right aortic arch with an aberrant left subclavian artery which arose from the right sided descending aorta. No vascular ring existed. Embryologically, in the double aortic arch plan of Edwards, interruption of the left arch proximal to the left common carotid artery and between the left ductus arteriosus and subclavian artery could explain the malformation (Fig. 41I-1D).[1–3,8] One would have to assume lack of proximal migration of the left subclavian artery so that the arterial duct enters the left dorsal aortic root proximal to the aberrant subclavian artery.

Associated cardiovascular abnormalities

A wide variety of congenital cardiac abnormalities have been described in association with isolation of the subclavian artery, or isolation of the innominate or left common carotid arteries. These abnormalities can occur in isolation, but they have been observed in patients with atrial and ventricular septal defects, atrioventricular septal defect, tetralogy of Fallot, hypoplastic left heart syndrome, pulmonary atresia and ventricular septal defect; coarctation of the aorta, transposition of the great arteries, interruption of the aortic arch; and aortic atresia with asplenia and heterotaxia.[1,2,4,6,7,9–17,19–35] Isolation of the left subclavian artery has been documented in a patient with Williams–Beuren syndrome.[33] In the setting of bilateral arterial ducts and isolation of the left subclavian artery, bilateral pulmonary artery obstruction has been noted.[15] Finally, there has been some discussion that isolation of the subclavian artery and innominate artery may be associated with chromosome 22q11 deletion.[23,35–39] There is not unanimity of opinion about this association.[37,39]

Outcome analysis

These uncommon vascular anomalies may go undiagnosed for many years, only to be recognized in the adult,[40] or they may be discovered during the investigation of congenital heart malformations. A pulse and blood pressure difference may not be apparent as long as the arterial duct between the pulmonary trunk and systemic artery remains widely patent. Once closure of the arterial duct has occurred, isolation of the subclavian artery may be recognized during the work-up for a weak arterial pulse ipsilateral to the isolated subclavian artery, and/or for a blood difference between the two upper extremities. Some patients will become symptomatic from a subclavian steal syn-

drome, while other patients may exhibit a discolored limb.[41] As with patients who have undergone a classical Blalock–Taussig shunt or left subclavian flap aortoplasty for repair of coarctation, relatively few patients develop clinical symptomatology of a steal. With inadequate arterial collateralization, the limb ipsilateral to the isolated subclavian artery may exhibit inadequate growth, or may be cooler than the contralateral limb. Claudication with exercise or prolonged use may occur if the involved limb is the dominant limb. A 36-year-old woman was investigated for increasing attacks of episodic dizziness, vertigo, and left upper limb claudication spanning 1 year.[41A] She was found to have a right aortic arch with isolation of the left brachiocephalic artery.

Isolation of the subclavian artery may result in a pulmonary artery steal.[17,42] This assumes patency of the arterial duct, and such a phenomenon has been described in the patient with tetralogy of Fallot as well as in the patient with transposition of the great arteries.[17,42] The patient with transposition of the great arteries described by Russell and her colleagues showed unilateral pulmonary edema and severe congestive heart failure secondary to the pulmonary steal.[42] At the time of the arterial switch operation, the isolated left subclavian artery was reanastomosed to the ascending aorta.[42] In this regard, the diagnosis of an isolated subclavian artery has evolved from angiographic imaging [1,2] to the echocardiography laboratory.[38,42,43] Isolation of the subclavian artery may confound cardiac catheterization when for technical or other reasons an approach from the right axillary artery is undertaken. It may further complicate construction of a Blalock–Taussig shunt, either classic or modified.[10,44] There is increasing experience with surgical reimplantation of the isolated subclavian artery.[14–16,38,42,43,45] Jones and coworkers have reported the use of the Gianturco–Grifka vascular occlusion device to close a moderate-sized patent arterial duct associated with isolation of the left subclavian artery.[46] Left vertebral artery "steal" through the moderate-sized patent arterial duct was eliminated by this transcatheter technique. Finally, isolation of the left subclavian artery has been documented in the patient with Williams–Beuren syndrome. In this situation when the pulse is weak, the etiology and therapy differ from the occlusive vascular arteriopathy typical of the Williams–Beuren syndrome (see also Chapter 14B).[47]

Pulmonary Ventricle to Pulmonary Artery Conduits

Introduction

During an operation to repair pulmonary atresia in 1965, Dr John Kirklin constructed a nonvalved conduit used to connect the right ventricle to the pulmonary artery by wrapping autologous pericardium around a Hegar dilator.[1] In 1966, Mr Donald Ross reported the use of a fresh aortic root allograft (or homograft) as a valved conduit for the same purpose.[2] These two sentinel events expanded the possibilities of repair for patients with complex congenital heart disease. They also initiated a search for the most physiologic and durable prosthetic device – a search that continues > 35 years later.

Conduit types

The conduits used by Drs Kirklin and Ross illustrate the two major types: nonvalved and valved. These two groups are further subdivided on the basis of their composition (Table 42-1). The sterilization process and preservation techniques are important variables that may affect conduit longevity. Sterilizing synthetic devices is simply and effectively accomplished by standard autoclaving, and long-term storage before implantation is similar to other surgical implants. However, tissue devices require more complex processing that may affect durability (Table 42-2). Although having the advantage of longer storage time, cryopreservation of allograft valves has been associated with reduced longevity when compared to those stored in antibiotic/nutrient solution.[3,4]

Indications for insertion

Anatomic lesions

Absence of a connection between the pulmonary ventricle and pulmonary artery (e.g. pulmonary atresia, truncus arteriosus) is an indication for a conduit. The conduit is native tissue if the pulmonary arteries can be sufficiently mobilized to allow a direct connection, although this usually requires an anterior patch to complete the connection. In addition, complex lesions with a component of pulmonary stenosis may require implantation of a conduit as part of a complete repair. For example, a conduit is placed between the right ventricle and pulmonary artery in patients undergoing the Rastelli operation for complete transposition of the great arteries (D-TGA), VSD, and pulmonary stenosis. A conduit may also be interposed between the left ventricle and pulmonary artery during repair of congenitally corrected transposition of the great arteries (L-TGA) when important pulmonary stenosis is present.

Residual lesions of the right ventricular outflow tract (RVOT)

In patients with defects such as tetralogy of Fallot, residual pulmonary insufficiency or stenosis may persist long after intracardiac repair. Patients with resultant right heart failure may benefit from pulmonary valve replacement with improvement in right ventricular function, functional class, and atrial arrhythmias.[5] However, the optimal timing for reintervention remains unknown. Therrien has suggested that patients having repaired tetralogy of Fallot with severe right ventricular dilation before valve replacement may be beyond full recovery of right ventricular function.[6] The inference that earlier valve replacement may preserve right ventricular function is tempered by the present limited durability of the valve.

Pulmonary autograft (Ross) operation

Patients with congenital or acquired aortic valve disease may be candidates for aortic valve replacement using the native pulmonary valve. After the native pulmonary valve and trunk are harvested for use in the aortic position, a conduit (usually an allograft) is inserted to restore continuity between the right ventricle and pulmonary artery.

Use of nonvalved conduits

A valve within the conduit is not always necessary. Because the valve is the primary source of late failure, avoiding a valve may defer subsequent conduit replacement. Patients suitable for a nonvalved conduit must have anatomically well developed, nonstenotic pulmonary arteries. The patient must also have low pulmonary vascular resistance, no anatomic or physiologic obstruction in the left atrium, and good systemic ventricular function.

Conduit reintervention

Most pulmonary devices fail as a result of progressive calcific stenosis, usually with the valve in a fixed, semi-open position.[7] The indications for reintervention for failing pulmonary prosthesis are progressive rise in outflow tact pressure gradient (with right ventricular pressure greater than two-thirds systemic pressure) or, less commonly, pulmonary regurgitation resulting in right heart failure. If the indication for initial valve replacement was right ventricular dilatation due to chronic pulmonary regurgitation, the hemodynamic burden of progressive conduit stenosis may be more poorly tolerated. Stenotic devices may be

improved by balloon dilation and stent placement. Although reintervention will be necessary, stenting may postpone reoperation for a number of months or even years.

Toronto experience

Since our first pulmonary conduit implant in 1966, we have inserted initial conduits into 930 patients. The most common diagnoses in these patients were tetralogy of Fallot, pulmonary atresia, and truncus arteriosus (Table 42-3). Including 32 additional patients referred from elsewhere for conduit replacement, 962 patients underwent a total of 1258 conduit operations. Operative risk for conduit implant and associated intracardiac repair was 16% for the overall experience. Operative risk persistently decreased over time and is currently 5%. The operative risk of replacement of an existing conduit is 4.0% and has not changed appreciably over time.

For the 930 initial implants, the most common devices were allograft valved conduits followed by xenograft valve implants and conduits (Table 42-4). Overall, implant structure included a tubular device containing a valve (609 patients, 66%), a pulmonary valve sutured orthotopically into the native RVOT (295 patients, 32%), or a direct connection using autologous tissue (26 patients, 3%). Only 27 patients had a nonvalved conduit at the initial operation. Patients having a monocusp patch inserted into the RVOT as part of an intracardiac repair are not included in these data.

Table 42-1 Classification of conduits

Non-valved	Valved
Tissue	Tissue
Pericardium	Aortic allograft
Autologous	Pulmonary allograft
Allograft	Xenograft
Xenograft	Stented
Autograft	Unstented
Interposition	Autograft (pericardial)
Direct connection	
Synthetic	Synthetic or composite
Dacron	Xenograft valve in Dacron tube
Polytetrafluoroethelene (PTFE)	Mechanical valve in Dacron tube

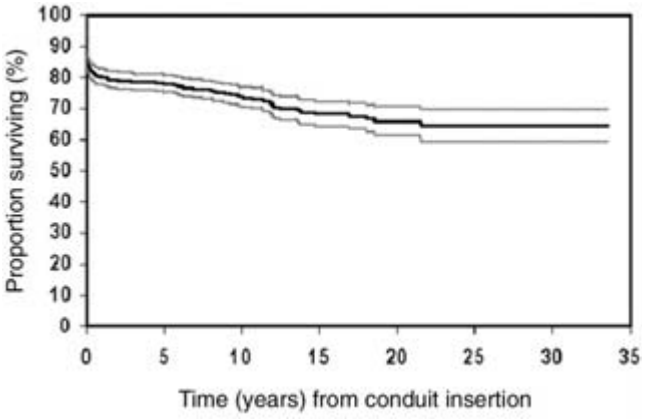

Fig. 42-1 Overall survival of 930 patients undergoing initial implantation of pulmonary conduit. The dark line represents the Kaplan–Meier survival estimate, and light lines enclose the 95% confidence interval.

Long-term function

Assessment of the durability of pulmonary prostheses is complicated by a number of factors. Marked variation in echocardiographic grading of pulmonary valve function exists, and differing definitions of conduit failure make interpretation of outcomes across institutions difficult. In addition, death occurring at some time after pulmonary prosthesis insertion may or may not be related to the function of the device. In either case, loss of the patient affects the assessment of prosthesis longevity. Overall survival amongst our patients is 80%, 74%, and 66% at 1, 10, and 20 years after conduit implant (Fig. 42-1). We have used conduit reoperation as a marker for failure. Although prosthesis function may have been sub-optimal for an undetermined period of time, reoperation represents a definitive end-point that is not especially qualitative. With reoperation as the only end-point (censoring dead patients at the time of death), overall freedom from conduit reoperation is 97%, 57%, and 29% at 1, 10, and 20 years after implantation (Fig. 42-2A). If death is included as an end-point, survival free of reoperation is 93%, 51%, and 23% at 1, 10, and 20 years (Fig. 42-2B). Although seemingly small in this instance, the magnitude of difference in Kaplan–Meier estimates resulting from the method of censoring is dependent upon the proportion of late deaths to reoperations. Long-term outcome data for non-fatal events produced in this manner are entirely dependent upon characteristics of the population that affect patient survival such as age and diagnosis. Therefore, outcome data for pulmonary conduits must be carefully interpreted bearing these considerations in mind.

A more descriptive method of analysing and reporting the outcomes of pulmonary conduits is the use of competing risks methodology.[8] Prosthesis reoperation and death represent two mutually exclusive outcomes and may be viewed as "competing" with one another. A patient who undergoes implantation of a pulmonary conduit is simultaneously at risk for more than one outcome and, at any time, is in one of three categories: reoperation for conduit failure, death before subsequent reoperation, and alive without reoperation. Competing risks determine the prevalence of each state over the follow-up time after implant (Fig. 42-3). At time 0, all patients have received a

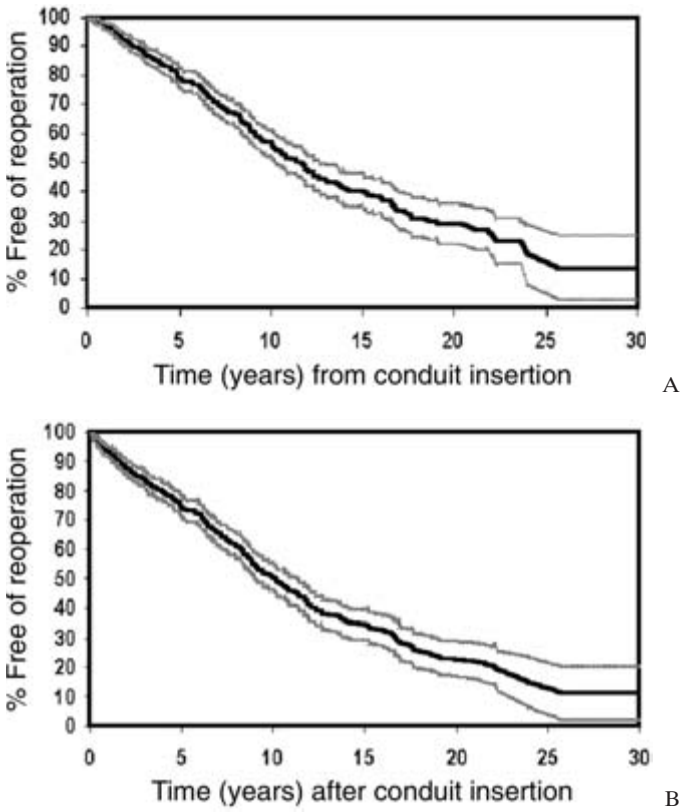

Fig. 42-2 Kaplan–Meier estimates of freedom from reoperation. Dark line, the Kaplan–Meier estimate; thin lines, 95% confidence interval. **A**. Death is not considered an end-point (patients are censored at the time of death). **B**. Death is considered an end-point in addition to reoperation such that survival free of reoperation is represented.

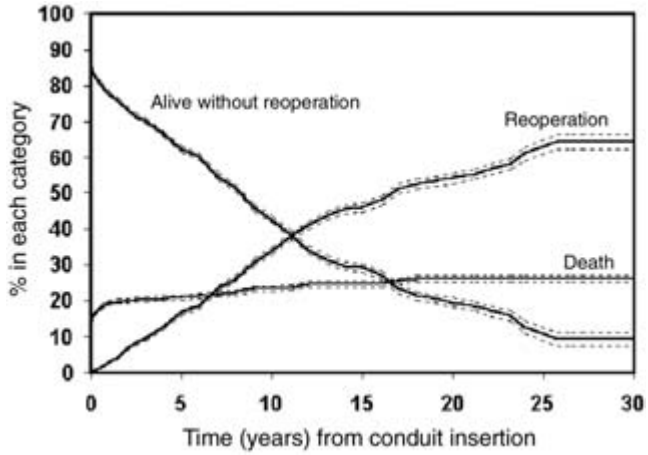

Fig. 42-3 Competing risks analysis of outcomes after initial pulmonary conduit insertion. The percentage of patients in one of three categories (reoperation, death, or alive without either outcome) is represented (vertical axis) at any time after conduit insertion (horizontal axis). At any given point in time, the sum of prevalence of all three states is 100%. For example, at 10 years after implant, 23% of patients have died, 34% have undergone reoperation for conduit failure, and 43% remain alive without reoperation.

conduit and are alive. At any time hereafter, the prevalence of death and conduit reoperation rises. There is an early increase in the prevalence of death corresponding to surgical mortality followed by a lower incidence of late deaths. At the same time, there is a steady increase in the prevalence of patients undergoing reoperation for conduit failure. By 20 years after conduit insertion, 26% of patients have died, 54% of patients have undergone reoperation, and only 20% of patients remain alive without undergoing reoperation. The application of competing risks methodology to the analysis of non-fatal events that compete with death gives the actual prevalence of outcomes expected over time.[9]

Durability following conduit replacement is not well assessed in the literature. In our experience, conduit durability is independent of the sequence of insertion (Fig. 42-4). First, second, third, and even fourth conduits have similar reoperation-free intervals. In a previous analysis, we found that patient age and device size are significant factors affecting long-term pulmonary prosthetic valve durability.[10] One might expect that patients returning for reoperation would be older and more capable of accepting larger devices – conferring improved conduit survival. However, the mean age of patients at initial implants is similar to the age of patients undergoing second or third implants. Successive allograft implantation has been implicated in reducing allograft longevity, potentially owing to a modulated immune response.[4,11] We analysed prosthesis survival in all 271 patients undergoing implantation of a second pulmonary implant. These patients were divided into four groups based on the sequence of allograft insertion: no allograft at first or second operation ($n = 109$), allograft at first operation replaced with non-allograft at second operation ($n = 62$), non-allograft at first operation replaced with allograft at second operation ($n = 64$), and allograft at first and second operation ($n = 36$). By this univariate analysis**,** survival of a second pulmonary device is not affected by the sequence of allograft placement, nor is durability different for patients who have or do not have an allograft (Fig. 42-5).

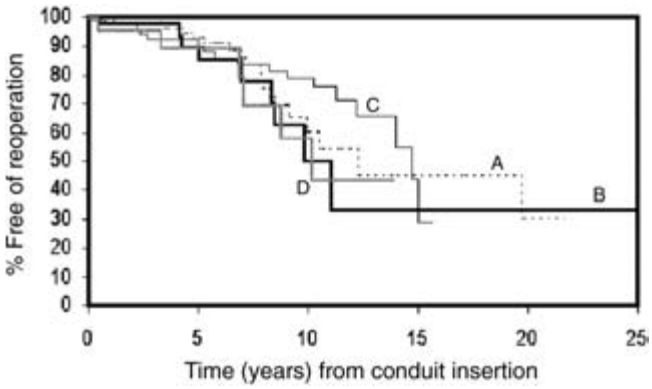

Fig. 42-5 Freedom from reoperation for 271 patients undergoing conduit reoperation (insertion of a second conduit). The patients have been grouped according to allograft sequence: A, non-allograft replaced by non-allograft ($n = 109$); B, allograft replaced by non-allograft ($n = 62$); C, non-allograft replaced by allograft ($n = 64$); D, allograft replaced by allograft ($n = 36$). No important inter-group differences in conduit longevity are observed.

Information from the literature

It is important to realize that patients with an incompetent, or even absent, pulmonary valve can survive without important limitations for many years. Shimazaki and colleagues demonstrated that patients with isolated congenital pulmonary valve incompetence remain asymptomatic for the first 3 decades of life.[12] Symptoms from right heart failure develop in 29% by age 40, beyond which the risk of developing symptoms rapidly increases. It is common to see a similar sequence among patients with pulmonary regurgitation after repair of tetralogy of Fallot who remain well until age 20–30 years. We have demonstrated that patient age and device size are important factors in determining the durability of pulmonary valves, and differences related to the various types of devices are less important.[10] Data from the Mayo Clinic have suggested that pulmonary allografts are more durable than aortic allografts when used in the pulmonary position, particularly for young children. Although allografts are advantageous for their technical ease of implantation, especially in infants, they do not have superior durability as measured by the interval free of reoperation. Stark demonstrated that allografts used at reoperation lasted less well than those implanted at initial operation.[4] We have not observed this trend in our experience as noted above. At reoperation, most obstructed conduits are excised and replaced with another one. As an alternative, the Mayo Clinic group devised a technique of autologous tissue reconstruction in which a xenograft pericardial patch is placed over the roof of the fibrous tissue bed of the explanted conduit.[13] They observed 100% freedom from reoperation for conduit obstruction at 10 years after operation. They purport that the technique simplifies conduit reoperation, provides a sizeable outflow tract, and yields excellent late results with low operative risk.

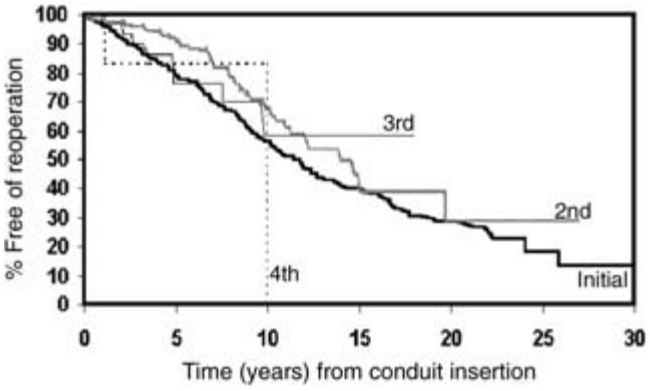

Fig. 42-4 Freedom from conduit reoperation by sequence of implant. There is no meaningful difference in conduit longevity observed for initial ($n = 930$), second ($n = 271$), third ($n = 47$), or fourth ($n = 8$) implants.

The Mayo Clinic published in 2003 its extensive experience addressing the late follow-up of 1095 patients undergoing an operation using pulmonary ventricle to pulmonary artery conduits.[13A] This entire experience included 1270 patients operated between April 1964 and January 2001, but this report concerned the 1095 patients operated before July 1992. The mean age of this group at operation was 9.6 ± 8.2 years. Diagnoses included pulmonary atresia/tetralogy of Fallot (459), transposition of the great arteries (232), common arterial trunk (193), double outlet right ventricle (121), corrected transposition (49), septated univentricular heart (36), and others (5). A porcine valved Dacron conduit was used in 730, homograft in 239, and non-valved

conduit in 126. They reported that early mortality decreased from 23.5% prior to 1980 to 3.7% for the most recent decade. Actuarial survival for early survivors at 10 and 20 years was 77.0 ± 1.5% and 59 ± 2.6%. On multivariate analysis, independent risk factors for late mortality included male gender, older age at operation, diagnosis of tranposition, corrected transposition, truncus, or univentrricular heart and a pulmonary ventricle/systemic ventricle pressure ratio < 0.72 ($P < 0.03$ for all). Freedom from reoperation for conduit failure at 10 and 20 years was 55.5% ± 2.0% and 31.9% ± 2.7%. On multivariate analysis, independent risk factors for conduit failure were homograft conduit, diagnosis of transposition, younger age at operation, and smaller conduit size ($P < 0.03$ for all).

The durability of allograft valves is disappointing, and their potential has not been fully realized in clinical practice. Conversely, preservation of semilunar valve function in transplanted hearts is invariably excellent. In this setting calcific degeneration is extraordinarily rare. Jonas and colleagues compared the histology of explanted allografts to valves retrieved from transplanted hearts at various intervals and observed that their histologic reaction is entirely different.[14] Although collagen is preserved, implanted cryopreserved allografts appear to be metabolically inactive. Lupinetti and associates observed the loss of endothelial cells from aortic and pulmonary allografts resulting from cryopreservation.[15] The viability of allograft cells may affect durability, but most evidence suggests that nonviable grafts have less immune reactivity and better survival.[16,17] Hawkins *et al.* confirmed the immune response generated by allograft insertion in children by demonstrating a measurable rise in panel reactive antibody titres.[18] O'Brien has led a multi-institutional effort in developing enzymatic decellularized xenografts and allografts using a process that preserves only the collagen matrix.[19] When implanted in animals, these experimental valves exhibit cellular and vascular ingrowth and have functioned for up to 1 year. Additionally, these valves have been shown to invoke no immune response as measured by panel reactive antibodies.[20] While this work is promising, the durability of decellularized grafts is presently unknown.

Other alternative valved conduits are being developed. Recent short-term results in which 71 patients with a bovine venous valved conduit were followed for 27 months compare favourably to allografts.[21] Hoerstrup and associates are developing a bio-engineered valved conduit that would obviate the immune reaction and have the potential for growth.[22] Hoerstrup and colleagues have used bio-absorbable polymers seeded with human umbilical cord cells to construct conduits with similar goals.[23] Mechanical valves in the pulmonary position should be mentioned. There are no large series reported, and experience is limited to anecdotal case reports of sudden, usually catastrophic, failure. The need for life-long anticoagulation further precludes serious consideration of pulmonary valve replacement using a mechanical prosthesis.

Pulmonary Veno-Occlusive Disease

Introduction

Pulmonary veno-occlusive disease is a rare cause of pulmonary hypertension. At the Evian WHO conference in 1998 pulmonary veno-occlusive disease was classified as a category of pulmonary venous hypertension. Other categories of pulmonary venous hypertension include left-sided atrial or ventricular heart disease, left-sided valvular heart disease and extrinsic compression of central pulmonary veins such as fibrosing mediastinitis and tumors.

Pulmonary veno-occlusive disease causes pulmonary hypertension with pulmonary edema. The patients are often extremely symptomatic at presentation and present a diagnostic dilemma.[1] The disease may be mistaken for primary pulmonary arterial hypertension until lung biopsy or autopsy reveals the correct diagnosis. Pulmonary vascular resistance is elevated secondary to postcapillary idiopathic diffuse fibrous obstruction of the intraparenchymal pulmonary venules and veins. Brown[2] and Heath[3] first used the term pulmonary veno-occlusive disease in 1966 to describe the clinical syndrome of progressive dyspnea, pulmonary edema, pulmonary hypertension and right heart failure without evidence of left heart disease. The pathological findings included diffuse small pulmonary vein muscularisation and obstruction without the typical arterial lesions associated with primary pulmonary arterial hypertensive vasculopathy. Before these descriptions there had been seven other similar cases reported.[2,4]

Pulmonary veno-occlusive disease accounts for about 10% of patients evaluated for primary pulmonary hypertension. The disease is, therefore, rare with an estimated incidence of 0.1–0.2 cases per million. Reported cases have an equal sex ratio, in contrast to primary pulmonary arterial hypertension. The median age at disease onset is 29 years (range 9 days to 68 years) and 30% of reported cases occur in patients < 17 years of age. In children, the sex ratio is 1:1.

Pulmonary veno-occlusive disease may occur in siblings and has been described in brothers[5–7] and brother and sister[8] thus excluding a sex linked transmission. Pulmonary veno-occlusive disease has not been described, as yet, in successive generations. However, at the Toronto Hospital for Sick Children we have seen the daughter (with biopsy proven primary pulmonary arterial hypertension) whose mother died of pulmonary veno-occlusive disease.

Histology

The histological features are typified by complete or partial obliteration of small pulmonary veins and venules by intimal proliferation and the deposition of collagen and reticular fibres (Fig. 43-1). The vein lumen may have the appearance of multiple septations which are thought to represent attempts at vein recanalization. Crescent shaped lesions or irregular thick septa divide the vein lumen into compartments and may extend from pulmonary veins into bronchial veins. There may be secondary thrombosis of the vein.[3,5,9–12] The small pulmonary veins are arterialized with medial hypertrophy. The extrapulmonary veins are usually normal although large intrapulmonary veins may be affected.[3,11,12] The paucity of normal intrapulmonary veins is a hallmark of the disease. The interlobular septa are markedly thickened containing congested lymphatics with many hemosiderin laden macrophages. These are the histological correlates of Kerley B lines and thickened septa visible on chest X-ray (Fig. 43-2) and CT scan (Figs 43-3, 43-4, 43-5) and evidence of post capillary obstruction with passive congestion, focal hemorrhage and hemosiderosis. Venous infarcts may occur adjacent to the interlobular septa.[13] Pulmonary artery morphometry demonstrates marked medial hypertrophy in pre and intra-acinar arteries.[9] However, advanced pulmonary artery changes of fibrinoid necrosis, angiomatoid or plexiform lesions are not found usually.

The diagnosis may not be apparent on lung biopsy, particularly if hematoxylin and eosin stains are used, as the distinction between arterialised vein and artery may be difficult. Movat's stain differentiates internal and external lamina well and helps to define the absence or paucity of normal pulmonary veins. It may be difficult, apart from the degree of venous remodeling to differentiate the changes of pulmonary veno-occlusive disease from mitral stenosis or fibrosing mediastinitis by histology alone.[9] Pulmonary vein intimal fibrosis may be seen in lung resected from young patients with spontaneous pneumothorax and is related to local and chronic inflammation rather than pulmonary venous hypertension.[14]

Pulmonary veno-occlusive disease and associated disease

Malignancy

Approximately 35 reported patients have developed pulmonary veno-occlusive disease in association with malignancy (Hodgkin's lymphoma)[15,16] or treatment of malignancy with chemotherapy,[17–19] radiation[20] or bone marrow transplantation (both allogeneic and autologous).[21–25] Pulmonary veno-occlusive disease has been frequently associated with bone marrow transplantation and high dose chemotherapy particu-

larly with agents such as bleomycin, BCNU, mitomycin–C.[17] In children it has been reported most often after treatment of acute lymphoblastic leukemia and gliomas. In adults it has been described during treatment of cerebral glioma, melanoma,[26] lung cancer treated with gemcitabine,[27] cervical[19] and gastric carcinoma.[28] Interestingly, although hepatic veno-occlusive disease also complicates cancer therapy and may be caused by monocrotaline (Jamaican "bush tea"), the latter

produces, in animal models, pulmonary arteriolar hypertension.[29] The association between hepatic and pulmonary veno-occlusive disease remains tenuous. There is one report of the development of pulmonary veno-occlusive disease occurring after resolution of hepatic veno-occlusive disease during cancer therapy.[21] However, pulmonary veno-occlusive disease occurs in association with interstitial pneumonitis during treatment of malignancy and the presence of pulmonary veno-occlusive disease may not be apparent until resolution of the pneumonitis after steroid therapy.[22,30] Pulmonary veno-occlusive disease has been reported with microangiopathic hemolytic anemia and chemotherapy for gastric adenocarcinoma[28] as well as after a second bone marrow transplantation for acute lymphoblastic leukemia.[24]

Autoimmune disease

Pulmonary veno-occlusive disease has been associated with the Felty's syndrome,[31] systemic lupus erythematosis,[32] CREST variant of scleroderma[33] syndrome, immune complex deposition, Raynaud's phenomenon,[34–37] following renal transplantation in a child for membranoproliferative glomerulonephritis,[38] hepatic cirrhosis (due to chronic active hepatitis) and celiac's disease.[7]

Despite the reports of pulmonary veno-occlusive disease with autoimmune disease and positive serology a direct link to immune mediated vascular lesions is lacking. Corrin *et al*.[39] demonstrated immune complexes in the alveolar wall but Hasleton *et al*.[7] could not find evidence of immune complex deposition in the vascualture of affected patients.

Other reported associations are with human immunodeficiency virus,[40,41] oral contraceptive use,[42] pregnancy,[43] preceding viral infection[44,12,45] and toxoplasmosis.[46]

Associations with congenital heart disease

Pulmonary veno-occlusive disease has been associated rarely with congenital heart disease other than patency of the foramen ovale. Biopsy proven pulmonary veno-occlusive disease has been described in a patient with pulmonary hypertension 5 years after aortic coarctation repair and resection of subaortic stenosis.[47] Pulmonary veno-occlusive disease has developed in the contralateral lung of a woman 4 years after left pneumonectomy for congenital unilateral pulmonary venous atresia.[48] Lang *et al.* described left sided pulmonary veno-occlusive disease in a patient with congenital unilateral absence of the right pulmonary artery.[49] In addition pulmonary veno-occlusive disease has been described in a patient with hypertrophic cardiomyopathy.[50]

Clinical features

The majority of patients present with dyspnea or syncope on exertion. The severity of symptoms is often out of keeping with the presenting clinical examination or resting hemodynamics. Other reported symptoms include orthopnea, paroxysmal nocturnal dyspnea, chest pain. Hemoptysis is rare, although presentation as life threatening pulmonary hemorrhage[51] and sudden infant death[52] are described. Physical examination reveals signs of pulmonary hypertension. Approximately one third of patients in the literature have displayed cyanosis at presentation. Clubbing was present in 5/11 patients in a recent series[53] yet only described in 3 prior cases.[54,30,55] Three reports comment on the absence of clubbing despite cyanosis.[45,3,12] Cyanosis and clubbing are unusual features of primary pulmonary arteriolar hypertension and their presence may alert one to the diagnosis of pulmonary veno-occlusive disease.

Chest X-ray

The chest X-ray demonstrates signs of pulmonary edema in 70% of reported cases. Kerley B lines (Fig. 43-2) are characteristic and represent septal thickening seen by CT scan. The distribution of pulmonary edema may be either diffuse or patchy and unlike mitral stenosis there is absence of upper zone pulmonary vein dilation and lower zone vasoconstriction. Pulmonary edema and septal lines may not be evident at presentation and may develop rapidly.[56] The right ventricle, right atrium and central pulmonary arteries are enlarged but the peripheral lung fields are not oligemic in contrast with primary arteriolar pulmonary hypertension or Eisenmenger's syndrome.[56]

The electrocardiogram

There are no characteristic ECG features of pulmonary veno-occlusive disease. The presence of right atrial enlargement, right ventricular hypertrophy with or without strain and right axis deviation do not aid in the differentiation from other causes of right ventricular hypertension.[2] The ECG may be within normal limits, even in the presence of dyspnea on exertion, but progresses rapidly.[36,57]

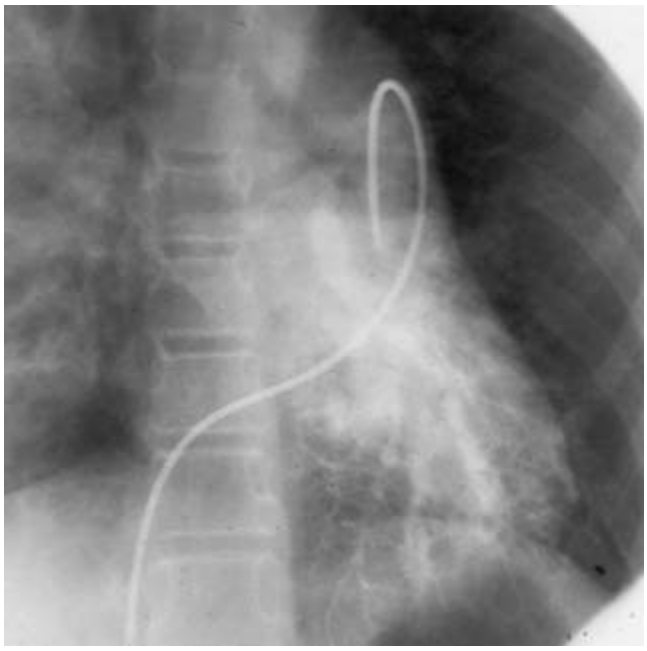
Echocardiography

Echocardiography is extremely useful in the diagnosis of all forms of pulmonary hypertension. However, there are no unique features of pulmonary veno-occlusive disease. Echocardiography can, however, rule out other causes of pulmonary hypertension with pulmonary edema such as extraparenchymal pulmonary vein compression, ostial pulmonary vein stenosis, cor triatriatum, supramitral stenosing ring, mitral valve stenosis, left atrial myxoma, cardiomyopathy and shunt lesions.

Cardiac catheterisation and angiography

The pulmonary artery pressures are elevated with median reported systolic and diastolic pressures of 75/36 mmHg (range 120/80–43/21) and mean pressure median of 56 mmHg (range 34–100). Right atrial pressures may be normal or elevated depending upon severity of disease and the presence of right heart failure. The characteristic hemodynamic feature is the variability of the pulmonary artery occlusion or "wedge" pressure. The pressure may be high, low or normal in the same patient depending on catheter position.[36] The pulmonary artery "wedge" pressure reflects left atrial pressure if there is an uninterrupted column of blood between pulmonary artery distal to the occluding balloon, or catheter tip, and the left atrium.[58] Pulmonary veno-occlusive disease is a patchy disease and "wedge" pressures will be normal (or reflective of left atrial pressure) if the catheter is "wedged" in a pulmonary artery proximal to unobstructed venules. However, if the catheter is "wedged" proximal to stenosed venules or completely occluded pulmonary venules the obtained pressure will not reflect left atrial

43.6



43.7

Figs 43-6, 43-7 Pulmonary artery wedge angiogram in pulmonary veno-occlusive disease. The peripheral pulmonary arteries are less tortuous with more peripheral haze than in pulmonary arterial disease.

pressure. In the former case the "wedge" pressure will be elevated and in the latter low.[58] If the catheter is "wedged" and flushed in this position there is an unusually rapid rise in pressure which falls slowly as the saline fails to clear because of the intervening obstructed venules.[54,59] The pulmonary artery wedge pressure is usually < 18 mmHg.[53]

In most cases of pulmonary veno-occlusive disease it is difficult to make the diagnosis unequivocally by angiography alone. Figures 43-6**,** 43-7**,** and 43-8 represent an exceptional patient. The described abnormalities include a delayed and patchy transit time of contrast from pulmonary artery to appearance in the left atrium.[56,60] The pulmonary artery may in extreme cases remain well opacified even after contrast appears in the aorta.[60] Pulmonary angiography may help to exclude chronic thromboembolic disease or peripheral pulmonary artery stenoses as a cause of proximal pulmonary artery hypertension. However, Katz *et al.* described pulmonary veno-occlusive disease presenting with pulmonary artery thrombosis.[43]

CT scan

High resolution chest CT scan may offer useful information and may help to differentiate pulmonary veno-occlusive disease from primary pulmonary arterial hypertension (Figs 43**-**3**,** 43**-**4**,** 43**-**5). The CT scan appearances that have been described include diffuse multifocal groundglass opacities, a mosaic pattern of attenuation with patchy areas of increased or decreased attenuation due to regional differences in perfusion, smooth (but occasionally nodular)[61] septal interlobular thickening, centrilobular nodules, mediastinal hilar adenopathy (in the absence of malignant disease) and pleural effusions.[61–64] Other CT findings, enlarged central pulmonary arteries with normal size airways, normal central pulmonary veins, right atrial and ventricular enlargement are present but do not help to differentiate pulmonary arterial from pulmonary veno-occlusive disease. However, demonstration of a normal left atrium and extrapulmonary veins excludes left heart inflow obstruction as a cause of pulmonary venous hypertension. Early disease may not show all of these features.[63] Mediastinal lymphadenopathy is an inconstant finding that has been described in approximately 8 patients without malignancy.[37,53,54,65,66] Mediastinal lymphadeopathy was not detected by CT scan in 8 patients reported by Swensen *et al.*[63] It may be difficult to differentiate pulmonary veno-occlusive disease from infiltrative lung disease

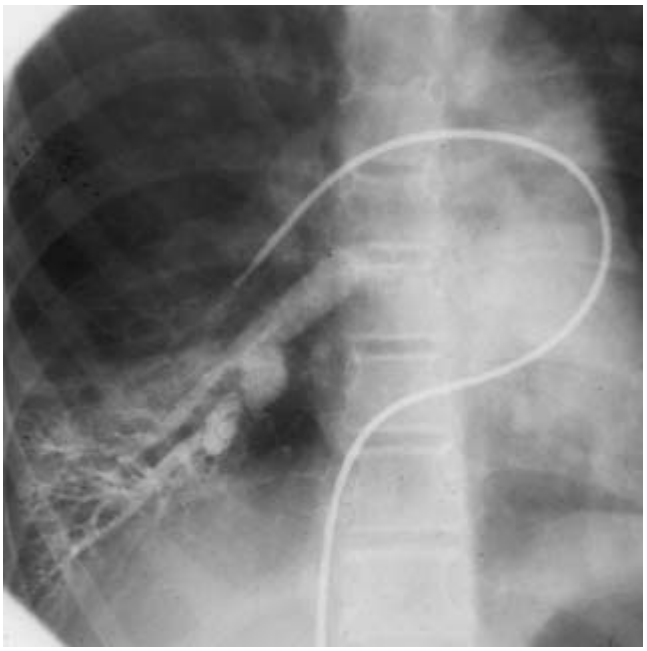


Fig. 43-8 The intraparenchymal pulmonary venous phase is distinctly abnormal with "bleeding" of the veins and delayed contrast clearance. The pulmonary venous connection with the left atrium is unobstructed.

by CT scan and mosaic attenuation due to vascular disease may be identified correctly in only a third of cases.[67]

V/Q Scan

Nuclear lung perfusion scan may demonstrate a segmental contour pattern,[68] small inhomogeneous sub-segmental matched or mismatched defects,[53] multiple mismatched segmental perfusion defects suggestive of thromboemboli[53,66] or nonspecific soft, fluffy inequalities of perfusion.[69] Lung perfusion scans may be entirely normal in 60% of cases.[53]

Pulmonary function tests

A severe impairment of single breath carbon monoxide diffusing capacity (D_{LCO}) especially with normal lung volumes and spirometry is an extremely useful test result in the differential diagnosis of primary pulmonary hypertension.[70] D_{LCO} has been reported in *c.* 40 patients with pulmonary veno-occlusive disease with a median D_{LCO} of 55% of predicted range (14–102%).[3,7,13,18,20,22,23,27,30,32,33,38,41,46,53,71–73] Approximately 50% of these patients have a severe reduction of D_{LCO} that is below 50% of predicted. In comparison patients with arterial pulmonary hypertension have D_{LCO} that is mildly reduced (69–70% predicted)[74] or normal.[75] Patients with pulmonary fibrosis and pulmonary hypertension will demonstrate a marked reduction in vital and total lung capacity, as well as, D_{LCO}.

Pulmonary function testing may yield mild restrictive, obstructive or combined patterns in a minority of patients with pulmonary veno-occlusive disease.[53]

Bronchoscopy

Bronchoscopy is not a routine test in the evaluation of pulmonary veno-occlusive disease. Nevertheless, the report by Matthews and Buchanan[71] is interesting for the insights it provides into the pathophysiology of pulmonary veno-occlusive disease and the interaction between airway and vasculature. They describe a sharp demarcation between normal main bronchi and intensely hyperemic lobar and segmental bronchi. They point out that the bronchial veins that drain the trachea and main bronchi return to the systemic venous circulation whereas bronchial veins draining lobar, segmental and peripheral bronchi return to pulmonary veins. In pulmonary veno-occlusive disease these bronchial veins become congested and enlarged. In severe cases the bronchial veins may act as a an alternative pathway from precapillary to postcapillary circulation and permit deoxygenated pulmonary arteriolar blood to bypass totally obstructed pulmonary venules in one lung segment to another. This may account in part for hypoxemia in patients with pulmonary veno-occlusive disease as disease progresses.

Differential diagnosis

It may be difficult to differentiate pulmonary veno-occluisve disease from primary pulmonary artery hypertension or chronic thromboembolic disease.[1] However, once the patient is recognised to have pulmonary hypertension with pulmonary edema, and cardiac conditions with elevated left atrial pressure are excluded further confirmation of the diagnosis requires lung biopsy. In children pulmonary veno-occlusive disease masquerades as interstitial lung disease especially if the CT scan is interpreted in isolation. Indeed in the review of Sondheimer 9/92 children who were thought to have interstitial lung disease had pulmoary veno-occlusive disease.[76] Other diseases which produce pulmonary venous obstruction and have been confused with pulmonary veno-occlusive disease include pulmonary capillary hemangiomatosis,[77] sarcoidosis,[78] Langerhans' cell granulomatosis,[79] left atrial tumour,[80] sclerosing mediastinitis,[9] pulmonary lymphangiomatosis. A syndrome of venulitis affecting pulmonary and systemic veins has been described.[81,82]

Treatment and outcome

The survival of patients after the diagnosis of pulmonary veno-occlusive disease is poor. Survival is generally supposed to be < 2 years from diagnosis[1] with a recent series of 11 patients reporting a 72% mortality in 1 year.[53] Survival of seven years without specific therapy has been reported.[36]

Pulmonary edema, which may be fatal, has been reported after prostacyclin infusion.[73,53] There is speculation that the dose of vasodilator may influence whether or not pulmonary edema is precipitated.[83] Nevertheless, symptomatic improvement and prolonged survival have been reported with prostacyclin, prazosin, dipyridamole and calcium-channel blockers.[26,53,54,84]

Pulmonary veno-occlusive disease related to cancer therapy may respond to steroids and warfarin.[23]

Most would recommend early listing for lung transplantation,[9,20,53,66,62] a cautious trial of vasodilator therapy, anticoagulation[2,54] and perhaps a short course of steroids.[1,21,54] A single prolonged response to azothioprine in a woman with associated autoimmune disease has been described.[35]

Since 1994 we have diagnosed three children with pulmonary veno-occlusive disease in the Toronto childhood pulmonary hypertension clinic. Two patients derived important symptomatic benefit from vasodilator therapy. One patient treated with diltiazem and subsequently intravenous prostacyclin survived 6 years from diagnosis and died awaiting transplantation. Another with rapidly progressive disease received initial benefit from continuous domiciliary nitric oxide inhalation but died 6 months after diagnosis. Another underwent bilateral lung transplantation 1 year after diagnosis but died from the sequelae of recurrent rejection within 1 year of transplantation.

Conclusion

Pulmonary veno-occlusive disease remains difficult to diagnose and treat. Differentiation from primary arteriolar pulmonary hypertension is challenging in those cases that do not demonstrate all the classic features of the disease. The disease may progress rapidly and at presentation early listing for lung transplantation seems to offer the best hope for prolonged survival.

Pulmonary Vascular Disease

Introduction

Pulmonary arterial hypertension is a devastating disease. The histological sequential changes are smooth muscle hypertrophy of the arterial wall, intimal proliferation, *in situ* thrombosis, small vessel occlusion and the formation of plexiform lesions. The cross-sectional area of the pulmonary vascular bed is diminished severely by small vessel obliteration. The progressive and sustained elevation in pulmonary vascular resistance leads to right heart insufficiency. After the onset of symptoms, the clinical course is unremitting with progressive right heart failure until death. Children suffer as badly as adults.[1] Until the last decade, conventional therapy was limited to digoxin, diuretics, calcium channel blockers and warfarin anticoagulation.[2,3] However, recent advances in vascular biology and molecular genetics have been translated rapidly into clinically relevant treatments.

The spectrum of pulmonary hypertension

Pulmonary hypertension is defined as a mean pulmonary artery pressure above 25 or 30 mmHg with exercise. At the Evian conference in 1998, the classification of pulmonary hypertension was revised to reflect clinical patterns of disease.[4,5] Primary pulmonary hypertension, which may be familial or sporadic, refers to pulmonary hypertension for which no cause can be identified. It is a form of pulmonary arterial hypertension. Other causes of pulmonary arterial hypertension include collagen vascular disease, congenital systemic to pulmonary shunts (Eisenmenger's), portal hypertension, HIV infection, exposure to drugs notably anorexigens (fenfluramine) and persistent pulmonary hypertension of the newborn. Pulmonary hypertension may be caused by pulmonary venous abnormalities (e.g. pulmonary veno-occlusive disease, left-sided heart disease) or associated with respiratory diseases and hypoxemia (e.g. alveolar capillary dysplasia, upper airway obstruction), chronic thrombotic or embolic disease (e.g. sickle cell disease) and finally disease directly affecting the pulmonary vasculature such as schistosomiasis and sarcoidosis.

The genetics of primary pulmonary hypertension

Familial vs. sporadic disease

Remarkable advances in the understanding of the genetics of primary pulmonary hypertension have emerged from the first clinical observations of familial pulmonary hypertension, 70 years ago, to the identification of the genetic mutations encoding bone morphogenetic protein receptor 2 (BMPR2).[6–8] The first report of the familial occurrence of primary pulmonary hypertension appears to have been in 1927.[9] Clarke *et al.*[9] described the clinical and autopsy findings of primary pulmonary hypertension in sisters (aged 5 and 8 years). They credited the suggestion of an "inherited aetiological factor" to Kidd in 1904.[9] However, Dresdale *et al*.[10] were the first to document familial transmission of the disease from one generation to the next. They described a woman and her son, who died from primary pulmonary hypertension aged 43 and 21 years old, respectively. The mother had, in addition, lost a brother ("at a young age") and sister (aged 31 years) from right heart failure, presumably owing to primary pulmonary hypertension. These early clinical observations describe many of the now established features of the inheritance of familial primary pulmonary hypertension including vertical transmission, genetic anticipation and the curious observation that within a family, affected males are clinically symptomatic and die younger than females.

The incidence of familial primary pulmonary hypertension would appear to be 1 to 2 cases per million with 6% of the cases in the NIH Registry fulfilling the criteria for the disease,[11] although subsequent observations suggest this is an underestimate with at least 50 affected families in the US.[12] Familial primary pulmonary hypertension differs from nonfamilial or sporadic forms of the disease with an earlier diagnosis after the onset of symptoms. Familial primary pulmonary hypertension is otherwise clinically indistinguishable from the sporadic form with a female to male ratio of 2:1 in adults but not children in whom the ratio is 1.3:1.

Familial primary pulmonary hypertension is transmitted vertically and in one family as many as five successive generations have been affected.[12] It may be transmitted from male to male and we have documented in the Toronto Childhood Pulmonary Hypertension Clinic the transmission of primary pulmonary hypertension from unaffected father to two daughters, each with a different mother. This mode of transmission excludes X linkage and is highly suggestive of an autosomal dominant gene. However, despite fulfilling criteria for autosomal dominant transmission, not all offspring are affected and not all carriers of the gene manifest the disease. Autosomal dominance with variable and lower penetration in males may explain the female preponderance of adults who carry the gene and manifest the disease.[13] Alternatively, the disease may affect males more severely at a younger age thus limiting the males who survive to adulthood. In addition fewer males are born to families who carry the gene, supposedly owing to selective wastage of the male fetus.[13]

The observation that within families with primary pulmonary hypertension successive generations are more severely affected at a younger age is termed genetic anticipation. Trinucleotide repeat amplification has been demonstrated in other diseases (e.g. fragile X syndrome) which show genetic anticipation, but not in primary pulmonary hypertension.

An association with major histocompatibility complexes in childhood familial hypertension suggests an autoimmune disease,[14] although antinuclear factors are usually negative in children.

Histology of familial, sporadic and Eisenmenger's vasculopathy

The histological features of familial pulmonary hypertensive arteriopathy appear to be heterogeneous and there is frequent coexistence of thrombotic and plexiform lesions within and among families.[15] Until the seminal publication of Lee *et al*.,[16] familial primary pulmonary hypertension appeared indistinguishable histologically from both sporadic primary pulmonary hypertension, and Eisenmenger's complex. Lee *et al*.[16] have demonstrated that the plexiform lesions of patients with familial primary pulmonary hypertension contain monoclonal proliferating endothelial cells in contrast to the polyclonal endothelial cell proliferation in secondary pulmonary hypertension (owing to congenital cardiac shunts). This is the first report of monoclonality of endothelial cells in a non-neoplastic vascular disease. The presence of monoclonal endothelial cell proliferation in primary pulmonary hypertension suggests that somatic gene alteration, similar to that present in a neoplastic process, may permit a clonal expansion of pulmonary endothelial cells.

Other histological subgroups of primary pulmonary hypertension include pulmonary veno-occlusive disease and pulmonary capillary hemangiomatosis: both may be familial but the inheritance seems to be distinct from the arteriopathy.[17]

Chromosome 2q33 and bone morphogenetic protein receptor 2

Independently, two groups have linked familial primary pulmonary hypertension with definitive logarithm of odds (LOD) scores to chromosome 2q33.[6–8] The detection of the haplotype associated with disease in a presumed to be unaffected sibling has led to the diagnosis of pulmonary hypertension.[18] Asymptomatic carriers may demonstrate an abnormal pulmonary vascular response to exercise.[19] Genetic testing offers the opportunity to at risk family members of close observation and early treatment if disease develops. However, more than just genotype is required for clinical disease to develop and interaction with environmental or other genetic traits is important. Thus, identification of haplotype insufficiency may provoke more anxiety than benefit.

Fifty per cent of familial and 25% of sporadic cases of primary pulmonary hypertension are caused by mutations in the gene encoding bone morphogenetic protein receptor 2 (BMPR2). Over 25 different mutations have been identified. A specific mutation is transmitted within a family.[20] BMPR2 is part of the transforming growth factor beta (TGF-β) pathway.[20–22] The TGF-(signaling pathway) is important in maintaining vascular and endothelial cell integrity. TGF-(inhibits vascular endothelial cell proliferation in culture), which may be pertinent to the observation that the plexiform lesion in patients with primary pulmonary hypertension represent abnormally proliferating monoclonal endothelial cells.[16] Mutations of a TGF-(type 1 receptor gene), activin-receptor-like kinase 1 (ALK1), and endoglin, an accessory protein of the TGF-(receptor complex), are present in hereditary hemorrhagic telangiectasia.[23] Patients with hereditary hemorrhagic telangiectasia may develop pulmonary arteriovenous malformations but very rarely pulmonary hypertension.[24] In fact patients with pulmonary arteriovenous malformations usually have low pulmonary artery pressures and resistances. However, Trembath *et al*. evaluated five kindreds with hereditary hemorrhagic telangiectasia and identified 10 patients with pulmonary hypertension (2 of 10 had pulmonary arteriovenous malformations) and mutations in ALK1.[25] This suggests that mutations in the TGF-(pathway) are associated with diverse vascular effects including abnormal dilatation, proliferation and small vessel occlusion. Interestingly, pulmonary artery smooth muscle cells from patients with primary pulmonary hypertension exhibit abnormal growth responses to TGF-β.[26] Gene transfer of vascular endothelial growth factor VEGF attenuates monocrotaline induced pulmonary hypertension mice and illustrates the potential impact of gene therapy.[27]

In summary, familial primary pulmonary hypertension is transmitted as an autosomal dominant gene with incomplete penetrance. From generation to generation there is genetic anticipation and a preponderance of affected adult females with a reduction in male progeny. The discovery of the genetic mutations of BMPR2 on chromosome 2q33 in 25% of sporadic and 50% of families with primary pulmonary hypertension will focus research efforts towards early detection of disease in asymptomatic carriers, better understanding of the triggers that result in clinical disease in the genetically predisposed and targeting the gene therapeutically.

Primary pulmonary arterial hypertension – clinical features

The etiology of primary pulmonary arterial hypertension is unknown. It tends to affect predominantly young people and its course is relentlessly fatal although isolated cases of spontaneous regression have been documented.[28,29] Children despite their young age often present with advanced disease[1,30] and median survival was 4 years[1] with a 37% survival at 1 year and 12.5% at 2.5 years.[30] Children present with similar pulmonary artery pressures to adults but a higher cardiac index. Right ventricular function is an important determinant of survival and a right atrial pressure of < 7.5 mmHg suggests a better outcome.[1] Similarly, a low mixed venous saturation does not bode well (< 63%) in either adults or children.[3,30,31] Children are more likely to respond to vasodilator therapy than adults (41% vs. 26%)[1] and may have a greater hemodynamic response.[32,33] In some studies hemodynamic response to vasodilators augurs a longer survival[30,33] but not all.[1] Despite this the histological profile of lung biopsy from children with primary pulmonary hypertension suggests increased vasoconstriction with more medial hypertrophy but fewer plexiform lesions and intimal fibrosis.[34]

Pulmonary hypertension in the absence of an intracardiac shunt is a difficult diagnosis to make in childhood and there may be a substantial delay from onset of symptoms to diagnosis. Common symptoms are dyspnea (often diagnosed as "asthma"), syncope or near syncope, generalized seizures, failure to thrive,

palpitations or cyanosis with exercise and leg edema. Exercise intolerance is almost always present. Chest pain is a rare presenting complaint in children (5.5%) as opposed to adults. Nevertheless, myocardial ischemia may be evident in children particularly when pressures rise above systemic and with exercise.

The chest radiograph provides valuable evidence of pulmonary hypertension with cardiac enlargement and characteristic enlargement of the proximal pulmonary arteries with distal pruning (Fig. 44-1). Pulmonary edema usually suggests pulmonary venous hypertension.

The electrocardiogram shows right atrial and ventricular hypertrophy with a strain pattern in 70–80% of patients.

Echocardiography is diagnostic of elevated right ventricular pressure and will provide evidence of a normal mitral valve and pulmonary veins. Other causes of right ventricular hypertension due to sub, valvar or supravalvar pulmonary stenosis are readily apparent. Small proximal pulmonary arteries with continuous distal color Doppler flow indicate multiple peripheral pulmonary artery obstructions. Intracardiac and extracardiac shunts can be excluded. Contrast saline echocardiography with visualization of the four chambers and descending aorta is useful to exclude right to left shunts and the appearance of microbubbles in the descending aorta may help to delineate a patent ductus arteriosus with reversed shunting.

Lung perfusion scanning is less likely to yield the diagnosis of chronic pulmonary emboli than in adults. Exceptions are children with ventriculo-atrial shunts or long-term intravenous lines who may develop pulmonary hypertension secondary to thromboemboli.[35] Nuclear perfusion scans are of value if single lung transplantation is to be considered in which case the lung with the poorest perfusion should be sacrificed. Cardiac catheterization and angiography are important in the evaluation and are discussed more fully below.

Fig. 44-1 Chest radiogram in primary pulmonary artery hypertension demonstrating right sided enlargement and dilated proximal pulmonary arteries with marked paucity of peripheral vessels.

Calcium channel blockers

In 1992, Rich *et al*.[2] demonstrated in 64 patients with primary pulmonary hypertension that high dose calcium channel blockade reduced pulmonary artery pressure and resistance by > 20% in 26% of patients. These patients were maintained on oral nifedipine or diltiazem with a 94% survival at 5 years and evidence of reduced regression of right ventricular hypertrophy and increased exercise tolerance and quality of life. Patients who responded with a fall in pulmonary vascular resistance but not pulmonary artery pressure did not experience a reduction in symptoms with long-term therapy. It is of note that calcium channel blockers may exacerbate right ventricular failure and need to be administered with caution.[36] Calcium channel blocker therapy is effective in only a minority of patients and has been superseded by newer agents.

Vasoactive mediators and pharmacological treatments

Prostacyclin is an endogenous vasoactive mediator, which promotes vasodilation, inhibits platelet aggregation and vascular smooth muscle proliferation. Thromboxane mediates opposite and generally deleterious effects in pulmonary vascular disease. The ratio of prostacyclin to thromboxane production is reduced in primary pulmonary hypertension,[37] the Eisenmenger complex and children with left to right intracardiac shunts but returns to normal after successful operative closure.[38]

Long-term prostacyclin infusion

Higenbottam *et al*. reported the beneficial effects of long-term prostacyclin in patients with primary pulmonary hypertension[39,40] Prolonged prostacyclin infusion was associated with an improvement in patient well-being, exercise tolerance and survival. This has subsequently been confirmed by other groups.[41,42] The results of long-term prostacyclin in patients awaiting heart–lung transplantation have been compared with historical controls. Survival at 1 year was improved and prostacyclin reduced mortality by 66%. Interestingly at 2 years there was no improvement over conventional therapy except in patients with more advanced disease (low mixed venous oxygen saturation and evidence of right ventricular dysfunction). In these patients long-term benefit was unrelated to the effects observed during acute administration raising the possibility that prolonged prostacyclin infusion works through mechanisms other than vasodilation such as inhibition of platelet aggregation and remodeling of the vascular wall.

Side-effects such as headache, cutaneous flushing and abdominal pain are seen usually transient and settle over 24 h but may reappear when the dose is increased.

Complications are related to the indwelling venous line, and delivery pump failure with two episodes of sepsis per patient per year. Dyspnea and syncope may occur during interruption of the infusion. The requirements for prostacyclin tend to increase with time[43] and dose titration to a normal cardiac index is required.[44] Nevertheless, prolonged intravenous prostacyclin therapy has a considerable impact with survival at 1, 2, and 3 years of 88%, 76%, and 63% which is significantly better than 59%, 46%, and 35% compared to historical controls. Baseline

predictors of survival include exercise tolerance, NYHA functional class, right atrial pressure and acute vasodilator response to adenosine or inhaled nitric oxide. After 1 year of therapy additional predictors of survival are cardiac index and mean pulmonary artery pressure.[44]

Continuous intravenously delivered prostacyclin improves exercise tolerance, pulmonary vascular hemodynamics and survival in pulmonary hypertension.[39,41,45,46] This therapy has revolutionized the chronic treatment of pulmonary hypertension. However, the drawbacks to continuous intravenous prostacyclin are the need for and complications of prolonged central venous access, the side-effects of the drug, and delivery system malfunction. Dangerous rebound effects occur if the infusion is interrupted. These problems are particularly cumbersome in the treatment of children and require the parents to acquire the skills of a critical care nurse, if the therapy is to succeed. Unsurprisingly many patients are reluctant to embark on such therapy. The development of alternative treatments is desperately needed. One approach has been to explore different delivery techniques for prostacyclin. These include the development of oral analogues, the aerosolisation of prostacyclin and the use of subcutaneously delivered prostacyclin. Beraprost is an orally active analogue of prostacyclin that has been shown to have beneficial short-term as well as long-term effects in pulmonary hypertension.[47,48] Functional class and 6-min walk improved by 63 metros after the addition of Beraprost to conventional therapy.[48] The improvement was similar to that observed after treatment with intravenously delivered prostacyclin and sustained over one year of therapy. However, there was only a small decrease in systolic pulmonary artery pressure and pulmonary vascular resistance was not measured. The side-effects of prostacyclin including facial flushing, arthralgia, muscle pain and nausea or diarrhea were common but clearly the catheter related morbidity was avoided.

There have been studies evaluating the effect of aerosolized prostacyclin, usually iloprost, in pulmonary hypertension. Inhaled iloprost is as effective as inhaled nitric oxide acutely, but there is no additive response to both agents.[49,50] Inhaled iloprost improves exercise capacity in severe pulmonary hypertension.[51–53] The findings are encouraging but do suggest that combination with an oral agent such as bosentan or sildenafil is likely to be the favored approach.[54]

Inhaled nitric oxide

Inhaled nitric oxide remains the acute pulmonary vasodilator of choice because it is selective for the pulmonary vascular bed, improves intrapulmonary shunt fraction and has a short half-life.[55] It is ideally suited for use in the cardiac catheterisation laboratory or in mechanically ventilated patients on the critical care unit with persistent pulmonary hypertension of the newborn or after cardiac surgery.[56–59] However, seemingly unjustified price increases driven by commercial exploitation of a natural gas may threaten the continued and widespread use of inhaled nitric oxide. Promising preliminary data are accumulating, using ingenious delivery systems, as experience is acquired with the chronic administration of inhaled nitric oxide to ambulatory patients. It suggests a beneficial reduction in pulmonary vascular resistance and improvement in patient symptoms with prolonged nitric oxide administration in both adults and children.[60–63] The drawbacks appear to be the need for continuous delivery and rebound pulmonary hypertension. Interestingly, a recent report suggests that although oxidative stress, as mirrored by increased lipid peroxidation, is elevated in patients suffering from pulmonary hypertension, inhaled nitric oxide does not increase peroxy nitrites further.[64]

Sildenafil

Sildenafil is a selective inhibitor of type V phosphodiesterase. Type V phosphodiesterase breaks down cyclic GMP and limits cGMP mediated nitric oxide vasodilation. The effects of phosphodiesterase inhibition are best known in the penile vascular bed, hence its use in the treatment of erectile dysfunction. However, there are high concentrations of the type V enzyme in the pulmonary vasculature. Preliminary reports suggest that sildenafil may have useful effects in pulmonary hypertension particularly in attenuating rebound pulmonary hypertension after discontinuing inhaled nitric oxide and in the chronic therapy of pulmonary hypertension.[65–68] Orally administered sildenafil abolishes hypoxic pulmonary vasoconstriction in humans.[69] Sildenafil is well tolerated and available as an oral preparation which makes it an attractive option to prostacyclin particularly for patients whose symptoms do not warrant continuous intravenous infusion. Sildenafil may prove to be a useful adjunctive therapy with nebulized prostacyclin or continuous inhalation of nitric oxide to prevent rebound pulmonary hypertension associated with inadvertent discontinuation or between inhalations of prostacyclin or analoges. Sildenafil produces acute and relatively selective pulmonary vasodilation and this appears to be maintained long term.[54,66–70] There may be synergistic or additive effects with prostacyclin resulting from elevation of both cAMP and cGMP.[54] Interestingly intrapulmonary shunting can be reduced with nebulised sildenafil, at least, in animal models.[71] and oral sildenafil appears to decrease intrapulmonary shunting in patients with lung fibrosis and secondary pulmonary hypertension.[72,73] Oral sildenafil would appear to be a selective pulmonary vasodilator in contrast to other intravenous or oral vasodilator.[72]

Endothelin receptor blockade

Endothelin is a powerful vasoconstrictor of certain vascular beds and promotes smooth muscle proliferation. There is accumulating evidence to suggest that abnormally high circulating endothelin levels may be deleterious in pulmonary vascular disorders. Increased endothelin levels, accompanied by reduced nitric oxide synthesis, have been implicated in the pathophysiology of pulmonary hypertension following cardiopulmonary bypass, persistent pulmonary hypertension of the newborn and Eisenmenger's syndrome.[58,74–78] Furthermore, continuous prostacyclin therapy in patients with primary pulmonary hypertension appears to improve pulmonary clearance of endothelin, *pari passu* with hemodynamic and clinical parameters.[79] The effects of endothelin are mediated through two receptor types ET_A and ET_B. ET_A is present on vascular smooth muscle cells and mediates vasoconstriction and proliferation, while ET_B is the predominant receptor type found on endothelial cells. When endothelin binds to ET_B receptors it promotes vasorelaxation through nitric oxide and prostacyclin release. This explains both the paradox of early work in which infusions of endothelin in normal mammals produce pulmonary vasodilation even in doses that produce systemic vasoconstriction and the importance of the endothelial cell in maintaining pulmonary vascular

homeostasis.[80] Thus it appears that in the damaged pulmonary vascular bed it is the ET_A receptor that predominates. It remains unsolved whether the appropriate pharmacological target should be the ET_A or ET_B receptor.[81] Nonselective ET receptor blockade may reduce the beneficial effects of ET_B (i.e. nitric oxide and prostacyclin release and endothelin clearance). Thus far, the most promising ET receptor blocker is the dual ET receptor blocker, bosentan. Intravenous bosentan reduces pulmonary artery pressure and resistance, but not selectively in patients with primary pulmonary hypertension.[82] Despite the non selective effects of intravenous bosentan, orally administered bosentan in two placebo-controlled studies improved exercise capacity, hemodynamics and symptoms over 16–20 weeks in patients with primary or pulmonary hypertension secondary to scleroderma.[83,84] The drug was well tolerated and free of side-effects apart from a dose dependent increase in liver enzymes. Elevations in hepatic enzymes reversed within 2–6 weeks of discontinuing bosentan.

Anticoagulation

A retrospective review of patients followed over a 15-year period suggested that patients who received warfarin had improved survival over those not receiving therapy.[3] There is histological evidence supporting the role of vessel thrombosis in primary pulmonary hypertension.[85] A substantial improvement in outcome has been demonstrated in patients who do not respond to calcium channel blockade and 1-, 2-, and 3-year survival is increased from 52%, 31%, and 31%, respectively, to 91%, 62%, and 47%.[2]

Other potential therapeutic agents

Abnormalities in potassium channels[86] and the extracellular matrix have been implicated in the pathobiology of pulmonary hypertension. However, despite demonstration of dramatic reversal of monocrotaline induced vascular changes in the rat by inhibition of matrix metalloproteinase and tenascin-C by serine elastase inhibitors these observations have not led, as yet, to therapeutic strategies applicable to human disease.[87–89]

Blade atrial septostomy

Cognizant of the fact that patients with the Eisenmenger reaction and pulmonary hypertensive patients with a patent foramen ovale tend to live longer than patients with primary pulmonary hypertension without intracardiac shunts.[90–92] Nihill,[93] Kerstein[94] and Sandoval[95] have reported blade septostomy in patients with advanced pulmonary hypertension. Animal studies[96] and experience with fenestrated Fontan operations have demonstrated that an interatrial communication allows decompression of a failing hypertensive right side with maintenance of cardiac output at the expense of a fall in systemic oxygen saturation but with an improvement in systemic oxygen delivery and reduction in symptoms of right sided failure. Blade atrial septostomy increases cardiac output (2.3 ± 0.6 to 4.3 ± 1.7 L/min/m^2) and systemic oxygen transport (450 ± 107 to 757 ± 325 mLO_2/min/m^2) despite a fall in systemic oxygen saturation (from 97.6 ± 2 to 91.0 ± 6.9%).[94] Survival at 1, 2, and 3 years was 80%, 73%, and 65% with significant improvement based on survival curves predicted from the equation developed by the NIH primary pulmonary hypertension registry data.[97] Blade atrial septostomy may benefit patients with recurrent syncope despite maximal medical therapy. However, it is not without risk. There is an early mortality, the patients require volume loading, elevation of hematocrit and inotropic support in the peri-procedural period.[94] Sandoval *et al*. suggested that graded, repeated balloon dilation of the septostomy might be the preferred approach.[95]

Lung transplantation

Despite advances in the understanding of pulmonary hypertension, lung transplantation is the last resort for patients who fail medical therapy for pulmonary vascular disease. The number of children who have received lung transplantation remains small. Nevertheless, Armitage *et al*.[98] suggest that actuarial 1-year survival in children is 73% and 90% for children with congenital heart disease. Armitage *et al*.[98] identified four issues they consider critical to the survival of children after lung transplantation. These were cytomegalovirus infection (23%), obliterative bronchiolitis (25%), post transplant lymphoproliferative disease (15%) and bronchial stenoses (9%). Ten year survival for lung transplantation in children is 30–40%.[99]

The timing of organ transplantation remains controversial. However, the success of medical therapy suggests that listing should no longer occur as soon as the diagnosis is made but rather wait a period of drug therapy. However, serious consideration of lung transplantation should occur with the onset of right ventricular failure or NYHA class IV status when mean survival time is < 6 months.[100] Absence of response to acute vasodilator therapy, suprasystemic pulmonary artery pressures, syncope or low cardiac output are signals of severe disease and should prompt careful assessment by the transplant team. Survival curves for children based on hemodynamics have been generated. The simplest devised by Clabby *et al.* suggests that if the right atrial mean pressure times the pulmonary vascular resistance index is < 160 survival will be better without lung transplantation.[1,101,102]

Summary

There have been remarkable advances in our understanding of the pathobiology of pulmonary hypertension. A region on chromosome 2 encoding bone morphogenetic receptor type 2 has been identified to underlie familial and many cases of sporadic primary pulmonary arterial hypertension. The vasoactive mediators, discovered and defined by vascular biologists, have been translated into promising treatments of human disease.

Prostacyclin, endothelin receptor blockers, sildenafil and nitric oxide have been applied therapeutically to limit, and occasionally reverse, the inexorable damage to the pulmonary circulation initiated by recently identified genetic and environmental triggers of pulmonary arterial hypertension.

Pulmonary hypertension secondary to congenital heart disease

Introduction

The functional and structural status of the pulmonary vascular bed plays a pivotal role in the presentation and outcome of the child with congenital and acquired cardiovascular disease. Assessment of the degree of pulmonary vasoconstriction rela-

tive to fixed pulmonary vascular obstruction is important in the management of the child with evidence of an elevated pulmonary vascular resistance. Recent advances in vascular biology have highlighted the essential role of the endothelium in the modulation of vessel tone in both the systemic and pulmonary circulations and abnormalities of endothelial function are considered important in the vascular pathology of a number of circulatory diseases.

Pulmonary hypertension and congenital heart disease

At birth the pulmonary artery pressure is close to the systemic pressure.[103] Within the first hours and days of life pulmonary artery pressure decreases rapidly due to a combination of vessel wall remodeling, functional maturation of the endothelial cell, differentiation of smooth muscle cell, recruitment of lung vessels and release of vasoactive mediators.[103–108] If successful transition of the pulmonary circulation occurs the pulmonary artery mean pressure falls to 10–20 mmHg and is similar to adult levels in the first three weeks of life.[109] In young children total pulmonary vascular resistance indexed is similar to adults.[110] Yet despite this physiological adaptation with reduction in pulmonary vascular resistance the ultrastructural appearance of smooth muscle cells does not closely resemble that of the adult until about 2 years of age.[111] This may account for the lability of the neonatal pulmonary vasculature. The normal development of the pulmonary vascular bed is altered in neonates with a large left to right shunt and pulmonary hypertension[105,112] and if the defect remains uncorrected can progress to obliterative pulmonary vascular obstructive disease. There is, however, great variability in this rate of progression. The type of congenital abnormality and the age of the patient are the two most important factors, which determine the onset of pulmonary vascular disease. For example, the progression of pulmonary vascular disease is slow in most children with an atrial septal defect in whom there is an increase in pulmonary blood flow without an increase in pressure. Only rarely will an atrial septal defect in childhood be associated with accelerated pulmonary vascular change.[113] Children with a large unrestrictive ventricular septal defect with both increased pulmonary flow and pressure develop pulmonary vascular changes more rapidly and should undergo correction by the first year of life.[112] Pulmonary vascular changes are accelerated in patients with transposition of the great arteries, especially if complicated by a ventricular septal defect, and severe obstructive intimal proliferation may be present at 6 months of age.[114,115] Even with the current policy of early neonatal repair there are reports of severe and fatal pulmonary vascular disease occurring after the arterial switch operation.[116]

Pulmonary artery pressure and vascular resistance may be elevated secondary to high pulmonary venous pressure due to elevated end diastolic left ventricular pressure, mitral stenosis or pulmonary vein obstruction. Typically patients with a high pulmonary venous pressure demonstrate marked vasoreactivity and if the underlying abnormality is corrected will respond favorably to vasodilator therapy and regression of the pulmonary vascular changes.[117] In general children with congenital mitral stenosis respond similarly.[118] However, on occasion presumably because the pulmonary vascular has always been exposed to high pressures unlike the situation in acquired disease the pulmonary vascular disease may be fixed.[55]

Heath and Edwards have described the classical progression of the pulmonary vasculature in subjects with congenital left to right shunt lesions.[119] They classified the progression from grade 1, medial hypertrophy with extension of smooth muscle into normally non-muscular arteries through to grade 6, the stage of necrotizing arteritis. Rabinovitch has described a more recent classification, which is clinically useful in the assessment of operability and is based on a quantitative morphometric analysis after the injection of a barium gelatin mixture into the lung tissue. Grade A is the appearance of muscle more peripherally than usual with or without medial hypertrophy of normally muscular vessels. Grade B is distal extension of muscle plus medial wall thickness 1.5–2 times normal (B mild) or more than two times normal (B severe). Grade C is grade B plus decreased density of peripheral arteries relative to alveoli with a < 50% decrease in density of peripheral arteries being grade C mild and a reduction of > 50% grade C severe. These grades have been correlated with both pulmonary artery wedge angiography[120] and pulmonary artery pressure and resistance.[121] Balloon occlusion pulmonary artery wedge angiography[120] allows the quantification of the pulmonary vascular disease by analysis of the rate of tapering of vessels over which the luminal diameter decreases from 2.5 to 1.5 mm, background haze and on deflation of the balloon the pulmonary recirculation time (Figs 44-2, 44-3, 44-4). It also provides excellent visualization of the pulmonary veins.

Endothelial cell dysfunction and its role in the pathophysiology of pulmonary hypertension

The endothelium situated between vascular smooth muscle and the vessel lumen is ideally located to influence vascular tone. Pulmonary endothelial cells when exposed to high shear stress from birth demonstrate structural abnormalities.[122] Functional abnormalities are thought to precede morphological damage raising the possibility that vasoactive mediators produced by the endothelium may contribute to the evolution of pulmonary vas-

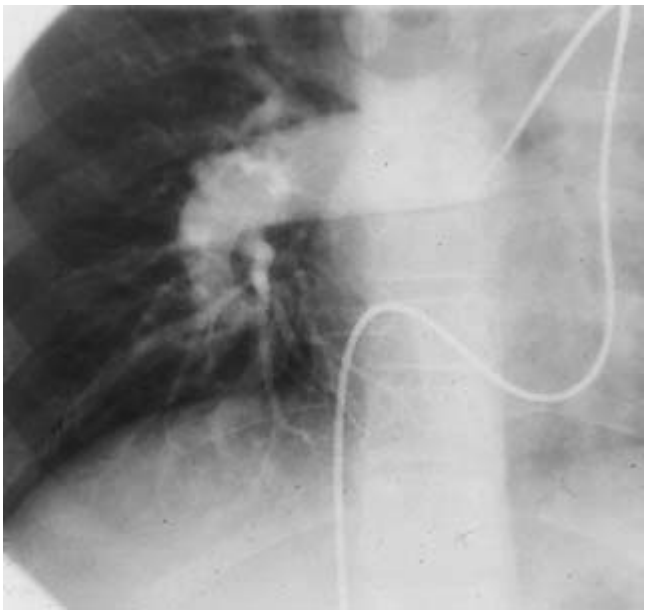

Fig. 44-2 Right pulmonary arteriogram demonstrating markedly enlarged proximal pulmonary artery that is typical of advanced pulmonary arterial hypertension.

Fig. 44-3 Left pulmonary artery balloon occlusion angiogram demonstrating tortous and "pruned" distal vessels with rapid tapering.

cular disease. The endothelium produces both vasodilators and vasoconstrictors and modulates the adhesion and aggregation of platelets. Thus the changes of pulmonary hypertensive disease including vasoconstriction, smooth muscle hypertrophy and vessel obliteration and could be mediated through an imbalance in the production of endothelial derived mediators subsequent to endothelial injury.

Thromboxane A2 and prostacyclin are both products of the arachidonic acid cascade but have opposing actions on smooth muscle and platelet aggregation. Thromboxane A2 is synthesized by activated platelets and by endothelial cells. It is a vasoconstrictor and proaggregatory. Prostacyclin is synthesized by pulmonary arterial endothelial cells but inhibits platelet aggregation (pGI2), relaxes vascular smooth muscle cells and inhibits their proliferation. Abnormal biosynthesis of prostacyclin and thromboxane with the balance favoring thromboxane A2 has been demonstrated in primary pulmonary hypertension,[37] and in young adults with fixed pulmonary vascular disease.[38] In young children with pulmonary hypertensive congenital heart disease and potentially reversible pulmonary vascular disease an abnormal ratio of thromboxane A2 to prostacyclin excretion is reversed following corrective surgery.[38,123]

Assessment

The rationale for the invasive assessment of pulmonary vascular resistance and the use of pharmacological agents to lower the pulmonary vascular resistance is based on the assumption that in the early stages of pulmonary vascular disease vasoconstriction precedes fixed luminal obstruction and that the institution of prolonged vasodilator therapy will at least retard the progress of the disease. Furthermore symptoms and decreased exercise tolerance are related to right ventricular function. Thus a decrease in right ventricular afterload by reducing pulmonary vascular resistance or allowing decompression of the right side through an atrial septal defect may improve the patient's lifestyle.

The assessment of pulmonary vascular resistance is not without difficulty, both theoretical and practical. The relationship between pressure and flow in the pulmonary circulation is complex. The resistance to flow is a function of the number, luminal area and length or the architecture of the vascular bed. In addition, pulmonary flow, left atrial pressure, pulmonary vascular tone, and critical closing pressure are important.

A measure of resistance to flow through the lung can be provided for by analogy with that used in an electrical circuit.

Pulmonary arteriolar resistance index **(**PARI) is calculated from PARI = mean PAp-LAp/Qp. PAp is the mean pulmonary artery pressure (mmHg) LAp is left atrial pressure and Qp is pulmonary blood flow in L/min per m^2. The latter is usually indexed for body surface area in children. Resistance units are expressed as Woods units (U/m^2) or multiplied by 80 to convert the value to dyn/s per cm^{-5}.

Thus a change in pulmonary arteriolar resistance index in response to administration of a vasodilator should reveal the vasoconstrictive component and potential for improvement with continued therapy. Indeed, there is a correlation with intimal area on lung biopsy and response to vasodilator.[124]

There are spontaneous variations in pulmonary arteriolar resistance index and over 6–8 hours in patients with pulmonary hypertension the variation was 6–13% and for pulmonary artery pressure 8%.[125,126] The response to vasodilator drugs is currently defined as follows.

- Responders experience a reduction in pulmonary vascular resistance ≥ 20% associated with reduction in mean pulmonary artery pressure ≥ 20 % and no change or an increase in cardiac index.
- Nonresponders: the reduction in pulmonary vascular resistance is ≥ 20% without significant reduction in mean pulmonary artery pressure.

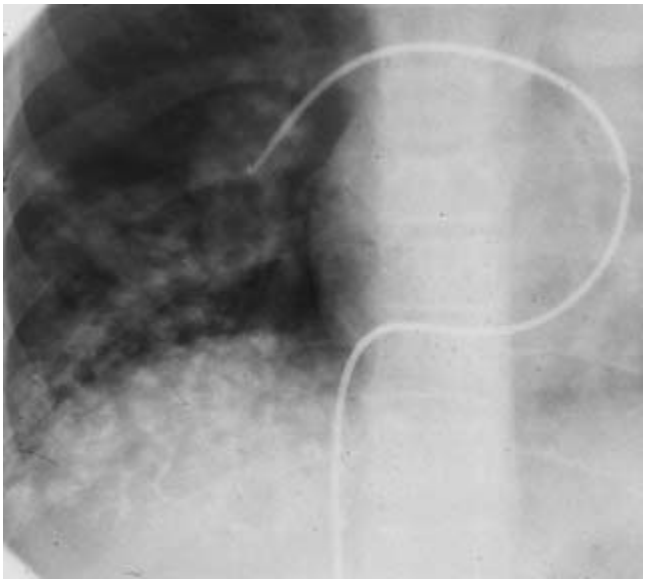

Fig. 44-4 Right pulmonary artery balloon occlusion angiogram late phase shows the patchy and diminished background haze often referred to as "puddling" of contrast.

- Unfavorable responders: symptomatic hypotension (or mean blood pressure fall of > 20%) with a reduction in cardiac index or an elevation in right atrial pressure.

Assessment of pulmonary vascular reactivity in young children is a challenging and demanding process.

Agents used for short-term testing

The ideal agent for short-term testing of pulmonary vascular responsiveness as recently suggested by Rubin,[31] would have better pulmonary dilating effects than systemic, a short half-life, and minimal adverse effects and be both easily and quickly administered, and predict reliably the effect of long-term administration of orally active agents.

Nitric oxide is simple to deliver either by mask or ventilator and as a trial of vasoreactivity over 15 min remains free of side-effects that might be encountered during long-term administration such as methemoglobinemia or nitrogen dioxide toxicity. Indeed no patient developed significant methemoglobinemia after a trial of nitric oxide nor was a level of nitrogen dioxide above 1 ppm registered during the administration. Thus nitric oxide gas fulfills many of the ideal characteristics, as recently suggested by Rubin required of a drug to test the acute responsiveness of the pulmonary circulation.[31] It has better pulmonary dilating effects than systemic, it has a short half-life, minimal adverse effects and it can be both easily and quickly administered. Whether it is able to predict reliably the effect of long-term administration of orally active agents awaits confirmation.

Treatment of acute pulmonary hypertensive crisis

Following surgery to correct congenital heart disease the pulmonary vascular bed may remain labile and susceptible to intense life threatening vasoconstriction.[127–130] The histological correlate of such hemodynamic changes has been described[112] and is due to strategically placed intimal proliferation in arteries accompanying terminal bronchi with a near normal appearance of peripheral intra-acinar arteries. Cardiopulmonary bypass may damage the endothelium,[131–133] attenuate the release of nitric oxide[134] or increase the thromboxane A2 to prostacyclin ratio[123] and increase the vulnerability of such patients to pulmonary vasoconstriction. The management of postoperative pulmonary artery hypertension is important because such patients have reversible pulmonary vascular changes. A successful strategy involves the adequate monitoring of pulmonary artery pressure, extending paralysis and anesthesia to blunt the stress response, which contributes to pulmonary vasoconstriction,[135] hyperventilation or alkalosis and more recently the judicious use of inhaled nitric oxide gas. Inhaled nitric oxide with its rapid onset of action and selectivity for the pulmonary circulation may become the treatment of choice for postoperative pulmonary hypertension and a number of reports asserting its efficacy have been published recently.[134,136–138]

Eisenmenger syndrome

In 1897 Victor Eisenmenger described the autopsy findings in a 32-year-old man with a large VSD and pulmonary hypertension.[139] However, Paul Wood in 1958 defined the disease in a masterly account, which remains relevant to our understanding of the clinical syndrome today.[140,141] Paul Wood used the term Eisenmenger syndrome to describe patients with pulmonary hypertension at systemic level, due to a high pulmonary vascular resistance (> 800 dyn/s per cm^{-5} or 10 Wood U/m^2) with a reversed or bidirectional shunt at aortopulmonary, ventricular or atrial level.[140,141] The term Eisenmenger complex refers specifically to patients in whom the fundamental lesion is a VSD.

Childhood Eisenmenger's syndrome is becoming increasingly rare. However, a glimpse into the severity of the problem that existed before early diagnosis and surgical correction of congenital heart defects were routinely available, can be gleaned from a cohort of patients aged 2 months to 16 years (median age 5.5 years) from Papua New Guinea between 1978 and 1994. The incidence of pulmonary vascular disease that precluded surgical repair of a shunt lesion was 21%.[142]

Clinical features

The clinical features of Eisenmenger syndrome are related to cyanosis, polycythemia, right heart failure (exacerbated by atrioventricular valve, and semilunar valve regurgitation) and pulmonary artery dilation. Patients with complex disease truncus arteriosus, atrioventricular septal defect, univentricular connection and transposition are symptomatic at a younger age and have poorer outcome. Patients with trisomy 21 also fare less well. In general symptoms are slowly progressive with age and become more prominent in late adolescence and adulthood. Effort intolerance is almost invariably present.

Cyanosis is at first present with exercise but becomes constant as the disease progresses and reflects in most cases the severity of the right to left shunt. The mean arterial oxygen saturation is saturation 83.6 ± 7.7% at presentation[143] Clubbing is invariable once cyanosis becomes persistent and may progress to hypertrophic osteoarthropathy with arthralgia and joint effusions.

Hematological abnormalities ensue from the hypoxemia, which results in erythrocytosis. Elevations in hemoglobin improve oxygen carrying capacity and patients are not usually symptomatic from the hyperviscosity syndrome until the hemoglobin level rises above 18–20 g/L. Symptoms attributed to hyperviscosity include headache, dizziness and visual disturbance including rarely central retinal vein occlusion.[144] Iron deficiency together with erythrocytosis aggravates the hyperviscosity and is a risk factor for cerebrovascular hemorrhage and stroke. Thrombocytopenia, prolonged bleeding times, abnormal PT and PTT with deficient clotting factors and abnormal fibrinolysis have been described and contribute to a bleeding diathesis and prolonged bleeding after surgical and dental procedures.

Hemoptysis (20.2%) may be due to intrapulmonary bleeding, ruptured bronchial artery or rupture of a pulmonary artery aneurysm from progressive central pulmonary artery dilation.

Pulmonary embolism and *in situ* thrombosis within dilated pulmonary arteries may also lead to hemoptysis (13.2%).[143,145]

Hyperuricemia is common due to increased production and decreased renal clearance of uric acid. Gout is less common affecting 13–23% of patients.[143,145]

Cholelithiasis and cholecystitis (15%) may occur from increased bilirubin in bile secretions secondary to high erythrocyte turnover.

Renal dysfunction with proteinuria (65%) may progress to the nephrotic syndrome and elevated serum creatinine is an independent risk factor for reduced survival.[143]

Cerebral complications include stroke (7.9%), cerebral abscess (3.7%) and occur at a mean age of 31.4 ± 15.7 and 24.1 ± 4.9 years respectively.[143]

Arrhythmias include isolated supraventricular ectopics and ventricular ectopics (42%), atrial flutter and fibrillation (35.5%).

In 22% of patients syncope or presyncope was related to ventricular tachycardia.[143]

Endocarditis (3.7%) may complicate outcome.[143]

Hoarseness and cough due to laryngeal nerve compression by dilated pulmonary arteries has been reported. Likewise, dilated pulmonary arteries may compress the left coronary artery with angina.[143,146–148]

Sudden death occurs in 30% of patients. Although the presence of a shunt and a "primed" ventricle since fetal life confers a survival benefit over patients with primary pulmonary hypertension as described by Hopkins and Waggoner,[92] the development of cardiac failure and death from the sequelae is common (40–50%). Cardiac failure is more common in complex Eisenmenger's and is due to AV valve, and/or semilunar valve stenosis and regurgitation.

Clinical outcome

Patients with the Eisenmenger syndrome require expert supervision.[149] All patients who present as adults with Eisenmenger syndrome escaped detection in childhood. However, the few studies, which include children, suggest that symptomatic children may deteriorate quickly and face all of the difficulties reported in young adults including sudden death, cardiac failure and hemoptysis.[150,151] It is the role of the pediatric cardiologist to emphasize lifestyle practices and therapies that appear to result in improved survival. It is paramount and the absolute responsibility of the pediatric cardiologist that the graduate from pediatric care be referred to a clinic for adults with congenital heart disease and provide a transcript of all the information relating to the patient. It is of note that 20% of deaths in an Eisenmenger cohort were associated with avoidable medical error.[149] Thus noncardiac surgery accounts for 23.5% of deaths.[143] Venesection should be performed sparingly for symptoms of polycythemia and in 20% of patients venesection leads to iron deficiency anemia which increases the risk of hemoptysis, stroke bleeding and adverse outcome.[143,145,152] In addition patients should receive counseling about the risks of pregnancy, high altitude, estrogens and anesthesia.[149] The use of vasodilators and anticoagulants need to be tailored to each patient by a physician experienced in the management of these patients as the balance between pulmonary vascular and systemic vascular resistance and the risks of bleeding and thrombosis are complex.

Oxygen therapy

An early study which was not randomized and included a heterogeneous group of patients seemed to indicate that oxygen therapy was beneficial in the Eisenmenger syndrome as all treated patients survived and 5 of 6 patients who did not receive oxygen treatment died.[153] However, these results have not been confirmed in a more recent study. Sandoval *et al*. based on the observation that the supine position resulted in desaturation in Eisenmenger patients undertook a 2-year randomized study of oxygen therapy in established Eisenmenger patients aged 20–50 years living at altitude. There was no change in hematology, exercise capacity or quality of life. The mean survival time was 20.7 months in both groups. The only factor associated with adverse outcome was a low MCV underscoring the harm that may ensue from venesection and the importance of treating iron deficiency. In addition oxygen delivered by nasal cannulae predisposes to epistaxis.[145]

Outcome

Survival of the patient with Eisenmenger syndrome is quite variable and risk factors include trisomy 21, complex underlying disease (worse for truncus, atrioventricular septal defect, univentricular hearts), anemia, pregnancy, sustained arryhthmias and elevated creatinine and need for noncardiac surgery.[145,143] In series that contain children the average age at death is 29 years with a 56% probability of surviving 10 years for a 20-year-old patient.[150] Whereas in adult clinics median survival at 18 yearss is 53 years with average age at death of 37 years ± 13.3.[154] Oya *et al.* report survival of 98% at 1 year, 77% at 5 years, 58% at 10 years and found that right atrial pressure and a cardiac index < 2.9 to be independent risk factors for death.[155] Patients with a simple VSD survive longer (42% at 25 years) with survival at 1, 2, and 3 years of 97%, 89%, and 77%.[91] Five-year survival for simple VSD is 91%, with truncus 67% and 34% for patients with single ventricle.[145]

Saha *et al.* report actuarial survivals at 5 years of 87%, at 10 years of 80%, and at 15 years of 77%.[156] Factors associated with poor prognosis included syncope at presentation, right atrial mean pressure above 8 mmHg and arterial oxygen saturation below 85%.[156]

Quality of life as reflected by employment in adult patients is variable with 53–57% (nontrisomy 21) holding full-time jobs.[143,145,150] However only 30% with complex disease enjoyed full-time employment vs. 89% with a VSD.

Pregnancy

In the 1960s pregnancy in women with Eisenmenger's syndrome carried a 27% mortality.[157] The risk of adverse outcome for mother and fetus remain high. The outcome of 84 pregnancies reported from six different centers was as follows: spontaneous abortion or stillbirth occurred in 25%, therapeutic abortion in 27%, premature or low birthweight baby in 26%, maternal death in 16% and maternal deterioration (including stroke, post partum hemorrhage, rapid decline in pulmonary vascular status) 54%.[143,145,150,151,155,156]

Therapeutic options for Eisenmenger's syndrome

Despite remarkable advances in the understanding of pulmonary vascular disease and advances in treatment for primary pulmonary arterial hypertension patients with established Eisenmenger's syndrome remain therapeutic orphans. However, demonstration of residual reactivity in these patients[55,158] is cause for cautious optimism that they will be included in future studies. However, recent observations on the regression of advanced pulmonary vascular disease in animal models[89,88] and the availability of oral therapies have stimulated renewed interest in devising treatment strategies for Eisenmenger's syndrome.

Rosenzweig *et al.* have used chronic infusions of prostacyclin to treat symptomatic Eisenmenger's and demonstrated an improvement in exercise tolerance and oxygen delivery but not arterial oxygen saturation.[159]

Although, surgical techniques for established Eisenmenger's syndrome with preparatory pulmonary artery banding and subsequent surgical closure of ventricular septal defect have been revisited (following an initial report in 1971 by Azzolina)[160] and stimulated considerable debate,[161–164] definitive follow-up data are awaited. Regression of medial hypertrophy and intimal proliferation is documented well after pulmonary pressure unloading in animals and humans.[165–167] It is unclear if advanced intimal fibrosis, fibrinoid necrosis or plexiform lesions regress after pulmonary artery banding. It is interesting to note that pulmonary vascular resistance may decrease after ductal ligation, despite plexiform arteriopathy on lung biopsy.[168]

The use of a double patch to close ventricular septal defects with hinge and fenestration to permit right to left but not left to right shunting has been reported in 18 patients with only one late death.[169] Baseline pulmonary vascular resistance was 11.4 Wood units (unindexed) and all patients were desaturated albeit with predominant left to right shunts. Pulmonary vascular reactivity results were not reported. It is, therefore, difficult to assess the degree of pulmonary vascular disease present in the patients reported by Novick *et al*.[169]

Lung transplantation and heart and lung transplantation

Thoracic organ transplantation is required only rarely for the child with Eisenmenger's syndrome, Nevertheless, according to Mendeloff *et al.* the outcomes are similar in children and adults with pulmonary hypertension secondary to congenital heart disease. Hospital mortality is 23% (16% required ECMO support) with a 5-year survival of 57%.[170]

Lung transplantation alone is possible for patients with ASD or PDA.[171] Conversely for Eisenmenger VSD survival is better with heart lung transplant rather than lung transplantation and VSD closure.[172] Patients with Eisenmenger syndrome wait on the list longer and the time when transplantation relative to remaining on the waiting list is less clear than for primary pulmonary hypertension.[173] Estimated survival for children with pulmonary hypertension and congenital heart disease is 88%, 88%, and 77% at 1, 2, and 5 years after cardiac catheterization.[101] In general if the product of mean right atrial pressure and indexed pulmonary vascular resistance is < 160, then survival is better without organ transplant.[101]

Heart and lung transplantation offers better survival than lung transplantation for most patients with Eisenmenger syndrome. Early mortality rates for adults after heart and lung transplantation are 16% for Eisenmenger syndrome vs. 13% for non-Eisenmenger. The 1-, 5- and 10-year survival rates are 73%, 51%, 28% for Eisenmenger compared with 74%, 48%, 26% for non-Eisenmenger.[174]

Summary

Patients with Eisenmenger syndrome have few therapeutic options. The hope must lie in early diagnosis and repair of congenital heart disease with appropriate and timely postoperative use of therapeutic agents that show promise in primary pulmonary arterial hypertension. The care of Eisenmenger patients should be cohorted in a clinic with experienced personnel who are willing to promote clinical trials of drugs that may improve the considerable morbidity associated with unrepaired and reversed central shunts.

Outcomes of Extracorporeal Membrane Oxygenation and Ventricular Assist for Congenital Heart Disease

Introduction

The first attempts at mechanical support of the circulation began with the pioneering work on cardiopulmonary bypass for open heart surgery in the 1950s, although this did not become widely used until the 1960s. The development of the membrane lung in the 1970s was a major advance in extracorporeal technology as it extended the safe period of cardiopulmonary bypass which, until then, had been limited by complications associated with the use of bubble oxygenators. It was only a matter of time before this technology was transferred from the cardiac surgery operating theatre to the intensive care unit. In 1971 the first case report was published of an adult patient with severe hypoxic respiratory failure (AHRF) who was successfully treated with extracorporeal membrane oxygenation (ECMO).[1] This was followed by case reports which included pediatric patients who had developed AHRF following repair of congenital heart defects. However, ECMO was largely abandoned in adult medicine following the publication of a trial showing no difference in survival in patients with AHRF treated with ECMO versus conventional ventilation.[2]

The first successful use of extracorporeal cardiac support in congenital heart disease is credited to Baffes *et al*.[3] who used it during palliative closed cardiac procedures as an emergency form of circulatory support, although these were of relatively short duration. Soeter *et al*.[4] in 1973 reported on the successful use of ECMO to support a child with cardiorespiratory failure following repair of tetralogy of Fallot. While the use of ECMO in congenital heart disease was sporadic at this time, there was increasing experience in applying the technique for the treatment of newborn infants with AHRF, pioneered by Bartlett and colleagues in Ann Arbor.[5] Through the 1970s and 1980s neonatal ECMO programmes were set up across North America and the Extracorporeal Life Support Organization (ELSO) was founded and a registry developed on outcomes following extracorporeal support. Over this period there were major advances in extracorporeal technology with the development of compact roller pump systems and small silicone membrane oxygenators suitable for neonatal use. To date over 16 000 term or near term infants with AHRF have been treated with ECMO with an 80% overall survival. The numbers of operational ECMO centers peaked in the early 1990s and since 1992 there has been a downward trend in the numbers of neonates placed on ECMO. This is probably due to a number of factors including the increased use of alternative ventilation strategies such as inhaled nitric oxide, high frequency oscillatory ventilation and a change in ventilation practice which recognizes that hyperventilation in persistent pulmonary hypertension of the newborn causes injury to the lung without changing the outcome. Over the same period there has been a major increase in the use of extracorporeal technology to support children with circulatory failure following repair of congenital heart disease,[6] as a bridge to heart and heart–lung transplantation[7] and in diseases of cardiac muscle (cardiomyopathy and myocarditis).[8] There have also been major new developments in circulatory assist devices so that other options apart from ECMO are now available for use in children with congenital and acquired heart disease. The chapter will describe the options available, the application of the technique and the outcomes.

Options for mechanical circulatory support

There are two options currently available for mechanical support in acute myocardial failure in children: a pumping device with an oxygenator (ECMO) or a ventricular assist device (VAD) to support either the left ventricle (LVAD), right ventricle (RVAD) or both ventricles (BIVAD) without an oxygenator. Ventricular assist devices can be extracorporeal (Biomedicus Centrifugal Pump) or paracorporeal (Berlin Heart, Thoratec) or implantable (Heart Mate).

The most extensive experience in children has been with the use of ECMO in the support of children with cardio-respiratory failure. The advantages of this technique are familiarity, the opportunity to avoid opening the sternum by using neck or groin vessels for cannulation, the provision of biventricular support with two peripheral cannulation sites and the presence of an oxygenator when hypoxemia complicates the clinical picture. The disadvantages are the presence of the oxygenator leads to increased destruction of platelets and greater heparin requirements resulting in bleeding, which may be particularly problematic if there has been a recent cardiotomy. There also may be inadequate unloading of the left heart which may necessitate a balloon or blade atrial septostomy or opening the sternum to place a left atrial vent. Although most centers use a roller pump system for ECMO, others prefer to use a centrifigal pump which allows for the flexibility to use either the ECMO or VAD option.[9] Using a VAD has the advantages of automatically unloading the left heart by draining the left side and since there is no oxygenator in the circuit, less anticoagulation requirements and destruction of platelets and fewer circuit related complications. The principal disadvantage is that cannulae have to be placed within the chest which may result in significant bleeding and the risk of infection.

Mechanical support systems

Roller pumps

The roller pump is the most commonly used in pediatric life support. In this system venous return is gravity dependent and therefore the pump has to be below the level of the patient. Venous return (inflow) is regulated by a distensible bladder, controlled by a servoregulatory mechanism attached to a spring loaded switching device. Interruption of venous inflow turns the pump off to prevent air entrainment. Forward flow is generated by compression of the circuit tubing between the roller heads and a back plate in the pump head housing. Volume is displaced as the roller heads travel the length of tubing within the pump head, known as the "raceway." The output of the pump is dependent on the diameter of the tubing, the rotations of the rollers per minute and the degree of occlusion. This is the gap between the roller and the back plate which, if significant, will allow backward flow of blood during rotation. The technical complications that can be seen with this system are blow out of the arterial circuit with occlusion of the distal arterial line and "raceway" rupture at the site of contact between the pump head and the circuit tubing.

A newer innovation in roller pump technology has been the development of the AREC (M pump) system which is non-occlusive. A silicone chamber is stretched over the outside of a three-pronged roller pump head. The pumping chamber fills passively by venous return and is less gravity dependent than the conventional roller pump system and the possibility of raceway rupture is eliminated.[10,11]

Centrifugal pumps

The centrifugal pump is gravity independent, venous inflow being driven by negative pressure generated at the pump head. The design principle is a constrained vortex produced by a series of cones rapidly spinning along a vertical axis. The mechanical energy comes from an electrical drive and coupled magnets. Line pressure is negative between the patient and pump head and care must be taken that this does not exceed –20 mmHg in order to prevent hemolysis. Excessive negative pressure can occur due to unfavorable venous cannula position, thrombus in the inflow or inadequate filling pressures in the patient. Venous line pressure is positive between the pump head and oxygenator. Flow is non-pulsatile and can be increased by increasing the rotational speed of the pump head. A reduction in venous return will reduce pump output which can be corrected either by increasing vascular volume or addressing the venous cannula position. Increasing the pump speed (rpm) in this situation without addressing problems of venous return will generate higher negative pressures in the inflow and increased hemolysis. This system operates most efficiently when the rpms are lowest for any given flow.

Oxygenators

There are two types of oxygenators currently in use for cardiac support, namely the membrane oxygenator or the hollow fibre types. The majority of the experience has been with the former. The design is based on a rolled spiral silicone membrane perfused with blood on one side and gas on the other. The transfer of gas to the blood phase depends on the partial pressure differences between the two, sweep gas flow, thickness and surface area of the membrane. Membranes are rated according to maximum allowable blood flow which, if exceeded, can lead to membrane rupture. Carbon dioxide clearance can be achieved by increasing the sweep gas flow. Differences in temperature between the blood and gas phase lead to water condensation in the gas compartment of the membrane which can result in decreased CO_2 clearance, as can clot formation on the blood side. The PaO_2 of the blood exiting the membrane is dependent on the FiO_2 of the sweep gas and the thickness of blood film.[12]

Membrane oxygenators are a source of considerable resistance to blood flow in the ECMO circuit. The pre- and post-membrane line pressures are monitored and an increase in the pressure drop (venous–arterial) may indicate thrombus formation within the membrane. A reduction in the pre- and post-membrane pressure difference may be due to kinking of the arterial line (increase in arterial line pressure), obstruction of the venous cannula (decrease in venous line pressure), an open bridge between the venous and arterial side of the circuit or, in the case of a roller pump, non-occlusion of the pump head.

A more recent innovation has been the introduction of the hollow fibre oxygenator. This consists of woven capillary tubes of microporous polypropylene. The internal resistance of these membranes is low and their gas exchange efficiency is very high. These attractive features are counterbalanced by their tendency to leak plasma which results in foaming after short intervals of use. They are frequently used in combination with heparin bonded circuits but the leakage problem makes them suitable only for short-term use.

Circuit components

The tubing commonly used in ECMO and other ventricular-assist circuits is polyvinyl with a diameter of either 1/4, 1/2, or 3/4 inch depending on the patient's size and circuit flows. The size of the tubing connectors and stop cocks used in the circuits depends on the tubing diameter, but constitute a source of increasing resistance and a site of potential thrombus formation within the circuit. A more recent innovation has been the introduction of heparin bonded circuits (Carmeda) which may decrease the need for heparin therapy. A circuit that bypasses the oxygenator, known as the bridge, directly connects the venous with the arterial line. This is opened when the arterial and venous cannulae have to be clamped either during an emergency or during the weaning process. During the normal ECMO run, the bridge is partially occluded with a U clamp, allowing for a minimal blood flow across the bridge in order to prevent stasis leading to thrombus formation.

Circulation of blood outside the body causes cooling. A heat exchanger is placed into the post membrane to reheat the blood temperature to 37ºC. These devices are controlled by a water bath, the temperature of which can also be lowered in situations where hypothermia may be required. The heat exchanger also incorporates a bubble-trap to collect any gas bubbles that escape from the membrane.

Circuit priming

Prior to initiation of mechanical support the circuit needs to be primed with fluid. First the circuit is flushed with CO_2 to eliminate any air. Line suction is applied to the gas ports of the membrane to bring the blood and gas phase of the membrane into

intimate contact. An electrolyte solution is added to the circuit in step-by-step fashion being careful to eliminate all air from the circuit. Albumin is then added to the prime in order to coat the blood contact side which helps to prevent platelet adhesion and activation. This solution is then replaced by a prime consisting of fresh frozen plasma and red blood cells, to which heparin is added. Bicarbonate or THAM is then added in order to normalize the pH and calcium to neutralize the effect of citrate. The prime is then circulated and the electrolyte and ionized calcium concentration measured prior to connection.

Some institutions now maintain a pre-primed ECMO or blood circuit for the institution of emergency mechanical support.[13] In this situation, the circuit is primed only with an electrolyte solution. Depending on the urgency of the situation, the circulatory support may be instituted with a clear prime, with the subsequent adjustment of the hematocrit, with the addition of red cells or hemofiltration to remove fluid.

Cannulation: sites and technique (ECMO and LVAD)

For the institution of ECMO most neonates and small children (<10 kg) are cannulated via the carotid artery and internal jugular vein as the femoral vessels are too small to accept adequate size cannulae. Older children, adolesents and adults are cannulated via the femoral vessels due to concerns of cerebral ischemia that may result from carotid cannulation.

The placement of cannulae in the neck vessels for ECMO is via an oblique incision in the right side of the neck with the venous cannula advanced so that the tip is in the mid right atrium and the tip of the arterial cannula at the junction of the innominate artery and the aorta arch. For femoral cannulation the venous cannula is advanced so that the tip is at the IVC right atrial junction and the arterial cannula is advanced so that the tip is at the aortic arch. When the trans-sternal approach is used for ECMO the venous cannula is placed directly into the right atrium with a left atrial vent and the arterial cannula is placed in the aortic arch. When LVAD is used the venous drainage cannula is placed through the left atrium or superior pulmonary vein.

Anticoagulation

During mechanical support a delicate balance has to be achieved between sufficient anticoagulation to prevent clotting within the circuit while minimizing hemorrhagic complications, which may be particularly problematic in the post-cardiotomy patients. Insufficient anticoagulation can also produce a DIC-type picture and further hemorrhage. The standard method for monitoring coagulation during mechanical support is the activated clotted time (ACT). The objective is to maintain the ACT usually in the range of 160–180 s. This is achieved by the infusion of standard heparin, in a dose of 20–30 U/kg/h. In situations where excessive bleeding occurs, the options are to reduce the heparin dose and run the ACTs in the lower range (160 s). There is also the option of using the anti-fibrinolyic drug aminocaproic acid (Amicar), for which there is extensive experience in the neonatal respiratory failure population.[14] The presence of an oxygenator in the circuit increases the need for heparin, which is one of the advantages that the LVAD system may have over ECMO. Some centers run the LVAD system without heparin in the post-cardiotomy situations where there is uncontrolled hemorrhage.

Patient management on mechanical support

Mechanical circulatory support is usually initiated at flow rates of 80–150 ml/kg/min depending on age, flows being higher in infants than in older children. The objective should be to achieve flows that provide adequate cerebral oxygenation and tissue perfusion with the preservation of end organ function. Objective markers of these would include a mixed venous saturation greater than 70%, a normal pH and lactate. One of the major objectives in mechanical support is to prevent ongoing myocardial injury. Therefore, care must be taken to avoid the heart overdistention which can occur with inadequate venous drainage. This will be evident by a high left-atrial pressure and the development of pulmonary edema on the chest x-ray. We have used echocardiography to assess the need for atrial decompression particularly after neck cannulation in the older child. Left atrial and left ventricular volume and function may be assessed serially and provide useful information to time left atrial decompression before pulmonary edema or hemorrhage become clinically manifest. If the sternum has not been opened percutaneous transcatheter left atrial decompression can be performed either in the cardiac catheterization laboratory or at the bedside. If transfer to the cardiac catheterization laboratory is an option, static balloon dilation of the atrial septum or blade septostomy can be performed after transeptal needle puncture (Fig. 45-1). Alternatively (especially if transfer to the catheterization laboratory is not feasible or urgent left atrial decompression is required) we have undertaken echocardiographically guided transeptal needle puncture. We have placed a long transvenous femoral sheath over the guidewire into the left atrium to decompress and monitor left atrial pressure as described by Ettedgui *et al*. and Ward *et al*.[15,16]

Clearly in the presence of a patent but restrictive foramen ovale then traditional echocardiographic bedside balloon atrial septostomy may be performed to good effect.[17,18]

Once bypass is established, a decision has to be made on the appropriate pulmonary management. In situations where LVAD is used full ventilatory support has to be maintained. The rules regarding ventilation settings on ECMO for cardiac support are different to those that apply in respiratory support and have to take into consideration the underlying heart function. A flat-line on the arterial trace indicates no cardiac contraction and therefore, the distal and proximal aorta, including the coronary arteries, will be perfused partly by fully saturated blood from the aortic cannula. The preservation of cardiac ejection, as is evidenced by arterial wave form, indicates there is opening and closure of the aortic valve. In this situation the coronary arteries are partially perfused by blood being ejected from the left ventricle.[19] It is therefore important that this blood be fully oxygenated by ventilating the lungs, so that any ongoing ischemic injury is minimized.

Another important factor in minimizing any ongoing myocardial injury is the maintenance of minimal afterload. The best marker of the effectiveness of this is the monitoring of the arterial pressure, which tends to rise with high-flow mechanical support.[20] This can be treated with intravenous vasodilator therapy in the form of phenoxybenzamine or nitroprusside with the objective of achieving an age appropriate mean arterial

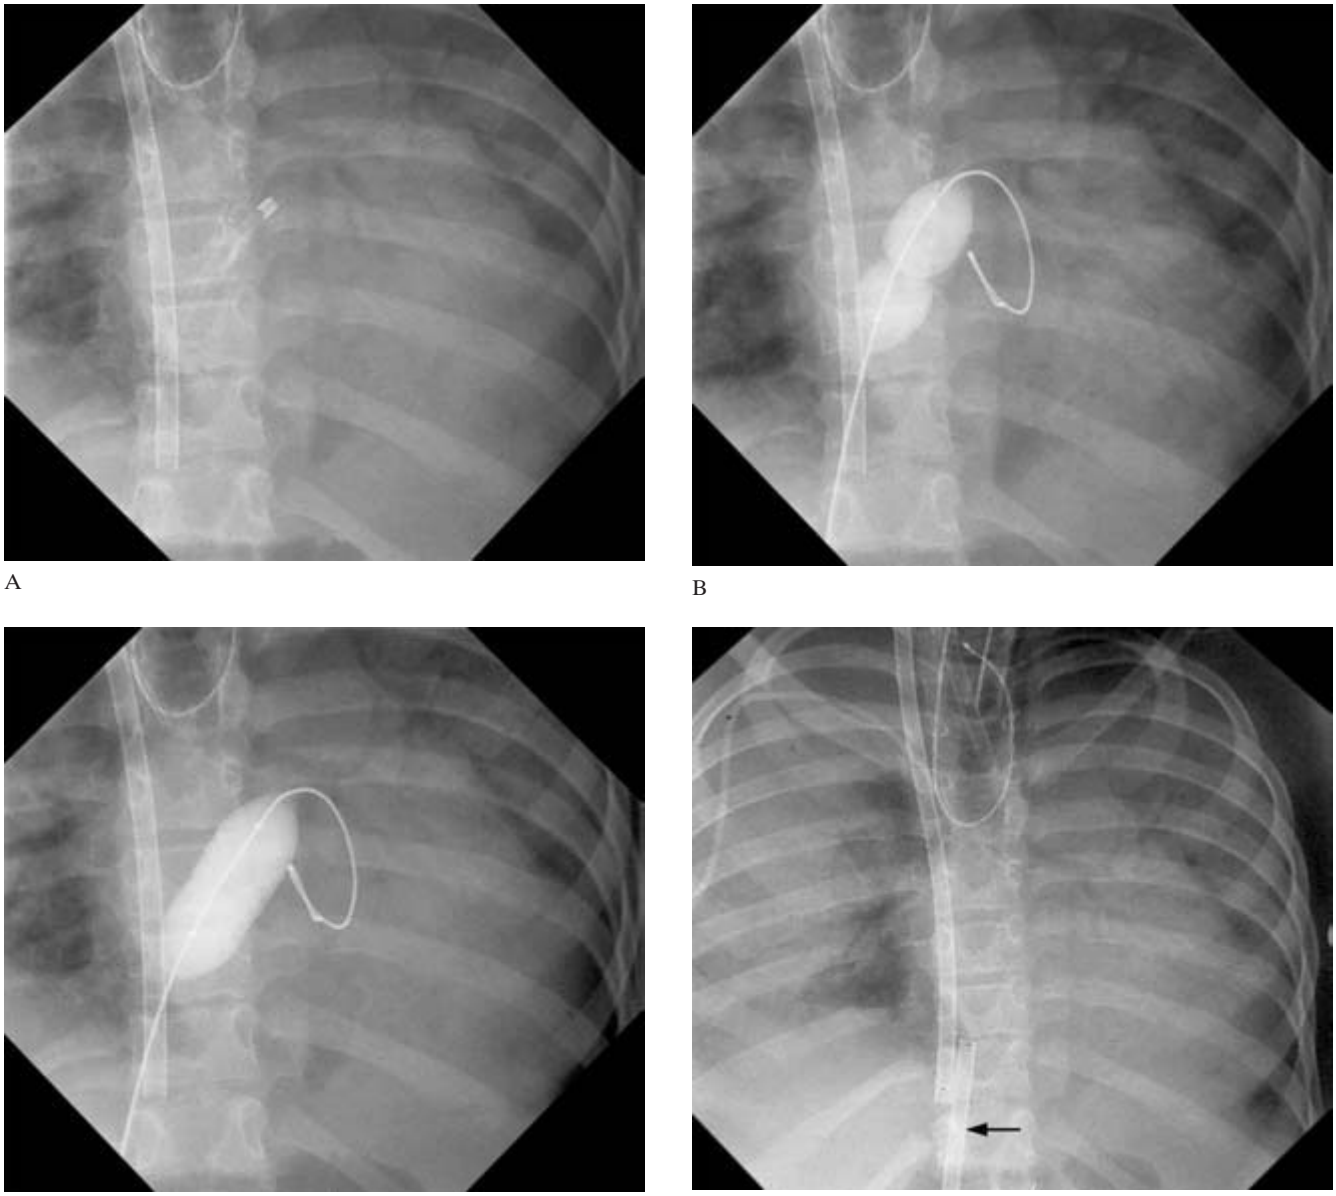

Fig. 45-1 Transcatheter percutaneous atrial septostomy. These figures demonstrate radio frequency wire perforation of the intact atrial septum (**A**), and progressive static dilation (**B**) of the perforation. Following left atrial decompression, a second venous cannula (arrow) is placed and positioned in the IVC from the femoral vein, to augment flow following urgent neck cannulation (**D**). Sternal opening is avoided.

pressure. The use of afterload reduction also reduces arterial line pressure in the circuit and enhances pump flow.

Other patient management issues

Sedation/analgesia

Patients on mechanical support require sedation and analgesia to alleviate the discomfort associated with cannulation or an open sternum. Neuromuscular blockade together with opiates and benzodiazepines are used for the first 24 h until satisfactory cannula position and circuit performance are established. After this time neuromuscular blockage should be discontinued in order to observe the patient's neurological status, in particular, the presence of any seizure activity, which could indicate neurological dysfunction.

Fluid management

Estimating fluid homeostasis on patients on mechanic support is very problematic. The estimation of fluid losses is complicated by leakage of fluid into tissues and hemorrhagic complications, frequently in the setting on ongoing renal dysfunction. The early placement of an ultrafiltration device allows for much better control of fluid balance. The control of water balance that this provides means that there can be early implementation of a nutritional support in the form of IV alimentation. The use of mechanical support does not preclude the use of the GI tract

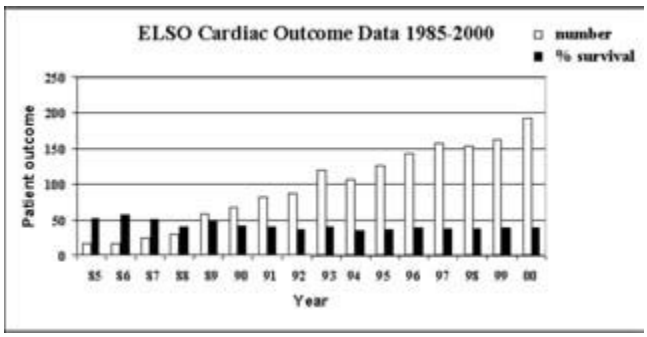

Fig. 45-2 Outcomes in ECLS reported to the ELSO Registry from 1985 to 2001.

and the use of trophic gut feeds to reduce the risk of nosocomial bacterial translation is recommended.[21,22]

Weaning from support

The decision on when to wean from support is based on assessment of ventricular function by cardiac echo. The process involves placing the patient on increasing doses of inotropes and vasodilator support and weaning back the bypass flow under echo control. This allows for an evaluation of the heart function under partial loading conditions. Once flows of 20–40 ml/kg/min have been achieved, the cannulae can be clamped and the patient tested under full loading conditions. During this period it is important to keep the patient fully heparinized, and to intermittently unclamp the cannulae to flush the lines, and prevent thrombus formation. It is also important to remember that patients on ECMO need to have their ventilation increased to full support during the weaning process. This does not apply to patients on the LVAD system who are already ventilated. The addition of inhaled nitric oxide can also be considered in patients placed on mechanical support for pulmonary hypertension and right-heart failure. When adequate cardiac function can be demonstrated to be sustained over a period of one-two hours without ECMO support, a decision can be taken regarding decannulation.

Indications

The indications for the institution of ECLS in congenital heart disease are not well defined. The most commonly described in the literature are: (a) failure to separate from cardiopulmonary bypass following repair with no residual anatomical defect; (b) failed resuscitation from cardiac arrest after surgical repair; (c) low output state in the postoperative period; (d) pulmonary hypertension post surgery; (e) acute hypoxic respiratory failure in a patient with congenital heart disease; (f) pre-operative stabilization. There can be little disputing that the first two of these represent absolute indications but a decision based on the remainder tends to be more subjective.

Outcome in extracorporeal life support

The outcomes following the initiation of ECLS in congenital heart disease depend on a number of factors which include the underlying heart defect, indications for initiation of support and complications during the support period (patient and technical). Exit from ECLS post surgical repair is either via recovery of myocardial function, death without weaning from support either due to myocardial failure or from non-cardiac complications, or via a transplant. Survival also needs to be evaluated on the basis of ICU survival, survival to hospital discharge and long-term outcome. Also, the outcome should be evaluated in relation to the number of times ECLS is used in the total institutional bypass series. The rates, which are not always reported, vary between 1% and 8.3%.[23–27] The source of these data comes from ELSO Registry, published case series and institutional experience. The overall survival to hospital discharge for cardiac support is 38% in 2937 cases reported to the ELSO Registry since 1985 (Fig. 45-2). Survival to hospital discharge in individual published case series varies between 25% and 60%[23–43] (Table 45-1).

Table 45-1 Outcome from ECLS in congenital heart disease

Author	ECMO number	LVAD number	Weaned	Survived to discharge	Per cent survival

Outcome related to cardiac diagnosis

It would appear logical that the underlying cardiac diagnosis is an important factor in determining outcome. Generally speaking the outcomes are worse with single ventricle palliation compared to biventricular repairs and this is confirmed in the ELSO Registry (Table 45-2). This database uses a simple classification of congenital defects into obstructive (right- or left-sided) lesions associated with left to right intracardiac shunts, cyanotic lesions with decreased or increased pulmonary blood flow, single ventricle lesions and other. Data are similar to those reported in some of the other larger single institutional experiences.[24,27,33] These have shown that the survival to hospital discharge is around 40% in patients undergoing biventricular repairs whereas it is generally < 30% in single ventricle lesions. ELSO Registry data are also reported by individual lesion and according to procedure (Table 45-3). If one scrutinizes the reported case series by procedure the most impressive survival is in patients with an anomalous left coronary artery (ALCA).[44–46] This is a lesion usually associated with very poor pre-operative myocardial function which is made worse by the ischemic injury from aortic cross clamping. There is a strong case to be made for an elective decision to ECMO or VAD support for the first few days in the expectation that function will improve.[47] The other end of the spectrum is the use of ECLS following the stage one palliation for hypoplastic left heart syndrome where the outcomes have been poor.[24] Until recently the approach has been to use ECMO support with the Blalock–Taussig shunt clipped in order to prevent run off into the pulmonary circulation and inadequate systemic flow. More promising results have now been published with a change in strategy to high flow (>150 ml/kg/min) support with a VAD and the left open.[26,48] The other procedures where ECLS support has been used include arterial switch for TGA, tetralogy and AVSD repair. Survival in these groups is similar at around 30–40%. The outcome data for ECLS for individual congenital heart lesions in the cardiac programme at the Hospital for Sick Children are shown in Table 45-4. The overall survival is 25%. This represents 1% of the total open heart surgical population. The prime indication for the institution of ECMO between 1991 and 2000 was failure to wean from CPB (40/65) followed by low cardiac output (14/65).

Outcomes related to indication for support

Survival to separation from ECLS is influenced by the indication for initiating that support. The three most commonly reported indications are failure to separate from cardiopulmonary bypass, a low cardiac output state (cardiogenic shock) in the postoperative period due to myocardial injury, or postoperative cardiac arrest. There have also been reports of patients with congenital heart disease placed on mechanical support preoperatively[11,35] as well as patients who develop acute hypoxic respiratory failure in the postoperative period where ECMO is used primarily as a respiratory support mode.[32] Poor survival is reported in some series of patients who fail to separate from CPB[24,27,39,40,49] with only 10% survival reported in one recent series.[33] These data should be interpreted in the light of the fact that with increased overall experience with the use of ECLS there is an increasing

Table 45-3 Outcome of ECLS in congenital heart disease classified by procedure

Procedure	Total number	Survived	Per cent survival
TGA arterial switch	210	81	39
TAPVR repair	101	44	44
Fontan operation	100	26	26
Stage 1 HLHS (Norwood)	188	53	28
AVSD repair	64	27	42
BCPS	19	7	37

tendency to initiate support in the operating room in patients with marginal function, rather than risk the development of profound low output leading to cardiac arrest in the postoperative period. This strategy has been used with success with neonates placed on LVAD after the stage I procedure for the hypoplastic left heart syndrome.[26,48] Better outcome figures are reported for ECLS initiated for low cardiac output in the postoperative period with 30% survival reported in one recent series.[33] However, a definition of what constitutes irreversible cardiogenic shock requiring ECLS support is somewhat subjective and may vary from center to center. Mixed venous oxygen saturation (SvO_2) and serial lactate measurement have been shown to be accurate predictors of death, poor outcome or the need for ECMO in several published studies.[50–53]

Several series are now reporting remarkably good survival where ECLS has been instituted following cardiac arrest, both in the post cardiotomy situation and in children with myocarditis and cardiomyopathies.[13,54] In the post cardiotomy situation, quick access to the thoracic vessels can be obtained by opening the sternum and good cerebral perfusion can be maintained by internal cardiac massage. There is an option to use either full ECMO support by placing cannulas in the right atrium and aorta or using LVAD by cannulating the left atrium. The advantage to using LVAD is that the left heart can be decompressed and if lung function is adequate, this may be a more attractive option in an emergency situation. Several centers, including our own, now have a pre-primed ECLS system available in the ICU for initiating emergency support.

When mechanical support is initiated for any of the above reasons, there should be a diligent search for anatomical defects that may have caused or contributed to the development of myocardial failure. In the first instance, this should be done with transesophageal echo followed by cardiac catheterization, if that is deemed necessary. The current ECLS support technologies include battery-operated pumps which facilitate transport either from the operating room or the intensive care unit to the cardiac catheterization laboratory. Uncorrected residual anatomical defects have been shown to have a much worse outcome with ECLS.[28,55] In the absence of this, low output or lack of function can be ascribed to myocardial failure which is potentially reversible. Recovery is frequently heralded by the return of the arterial waveform on the arterial line trace. Patients who fail to demonstrate return of function by 72 h are unlikely to separate from ECLS and the only options available are removal of life support or listing for heart transplantation. While the latter is the more attractive option, limitations of donor organ supply and the ability to preserve end organ function after more than seven days on mechanical support will influence the decision.

Investigation of residual anatomical lesions

ECMO support of the patient with critically decreased cardiac function has proved an invaluable adjunctive therapy until return of cardiac function or as a bridge to transplantation in patients with primary myocardial failure. However, the benefits of ECMO support after repair of congenital heart defects or as rescue therapy for acute postoperative collapse are less clear. Uncertainties about the benefit of prolonged expensive therapy remain. However, it is agreed generally that the presence of residual anatomic lesions requires prompt and urgent evaluation. Transesophageal echocardiography offers excellent visualization of most postoperative intracardiac anatomy as well as assessment of cardiac function during weaning of mechanical cardiac support. Indeed, the extent of cardiac dysfunction, dilation and mitral and aortic regurgitation may not be fully appreciated until TEE is performed with gradual reduction in circuit flow rates. This information is useful to determine a rational weaning strategy using inotropes, vasopressors, vasodilators and volume loading. However, TEE provides limited information about pulmonary artery stenoses particularly distal obstructions, BT shunt flow, coronary artery obstruction and occasionally aortic arch obstruction. This information is particularly pertinent to the survival of the patient with low cardiac output following the Norwood stage 1 procedure (Fig. 45-3). We have performed early cardiac catheterization in all patients who require postoperative ECMO support if the TEE does not rule out reversible hemodynamically significant lesions and spontaneous improvement in cardiac function fails to occur. Since 1990 we have taken 12 postoperative patients to the cardiac catheterization laboratory without major complications related to the procedure or transport (Fig. 45-4). In 6/12 (50%) angiography provided important additional information unsuspected or inadequately clarified by echocardiography. However, only

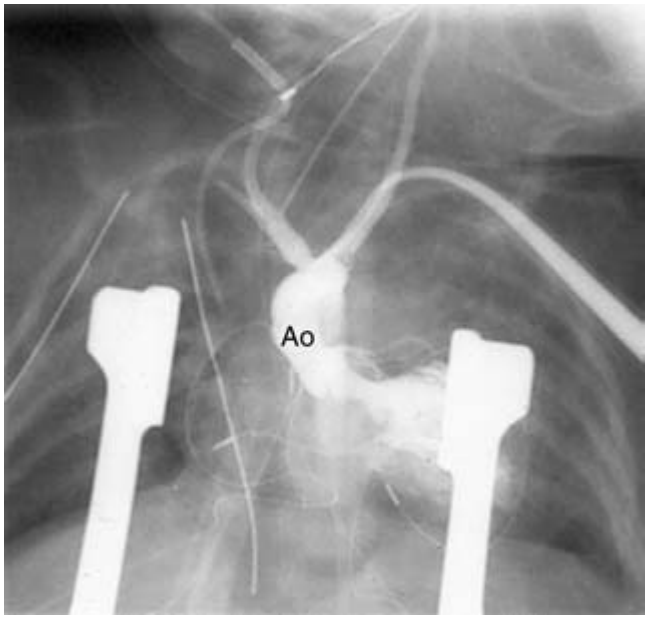

Fig. 45–3 Aortography, using the arterial cannula in a patient on ECMO with aortic incompetence. Ao, aorta.

4/12 survived weaning from ECMO support with 2/12 surviving long term (1 required cardiac transplantation following irreversible myocardial infarction after acute thrombotic obstruction to the left anterior descending artery and 1 required revision of native aortic to neo aortic anastomosis after stage 1 Norwood to relieve precoronary artery obstruction). Following revision the patient was successfully decannulated and has completed stage 3 (Fontan) with good ventricular function.[56] Cardiac catheterization and angiography can be performed safely and should be part of the evaluation algorithm of the postcardiotomy patient on ECMO.

Outcomes related to noncardiac issues

Survival following the initiation of mechanical support is dependent on more than return of cardiac function. The single most important factor that determines long-term survival and ongoing morbidity is neurological damage.[27,33] This may be caused by inadequate cerebral perfusion secondary to low output or cardiac arrest, cerebral infarction secondary to thrombus or air emboli from the circuit and cerebral hemorrhage related to anticoagulation plus or minus too high a cerebral perfusion pressure. The first indication of cerebral injury post initiation of mechanical support is frequently a development of seizure activity. In infants, the presence of a cerebral hemorrhage or infarction can be confirmed by a bedside cranial ultrasound. Neuroimaging studies in older children are more difficult to perform. Neurological injury is the most common reason for early termination of mechanical support.

The outcome in patients where ECMO is used in the postoperative period to treat acute hypoxemia depends on the reversibility of the lung disease, assuming that there are no residual cardiac problems. The overall survival in the ELSO Registry for children outside the newborn period treated with ECMO for AHRF is 40–50% survival. However, it is important to note that acute pulmonary failure outside the newborn period is not a rapidly reversible situation with a short duration of ECMO support. Average times on ECMO are usually a week to 10 days, which is considerably longer than when mechanical support is used for acute cardiac failure.

Other important factors that influence outcome following mechanical support are the development of multi-organ failure, particularly renal failure.[25,27,33,41,57] In the case series reported by Duncan[33] patients who had preserved kidney function as evidenced by ongoing urine output had a higher survival rate than those who became anuric. Survival in the postcardiotomy patients is also influenced by the amount of hemorrhage which, with the ongoing need for anticoagulation, can be very significant.[41,58] In the largest published series by Duncan[33] nonsurvivors had a nearly twofold greater blood loss than survivors.

Outcomes related to complications

Complications associated with the use of ECLS can be divided into patient related and technical complications. These are listed in Tables 45-5 and 45-6. Technical complications are lowest in programmes that have a trained ECLS team with a significant caseload volume to keep up their technical skills. The worse outcomes will be seen in small volume congenital heart programmes where ECMO is used only occasionally and the patient managed by personnel put together on an ad hoc basis rather than by a trained and experience team. Generally speaking, a minimum of 10 ECLS cases per year are required to maintain standards.

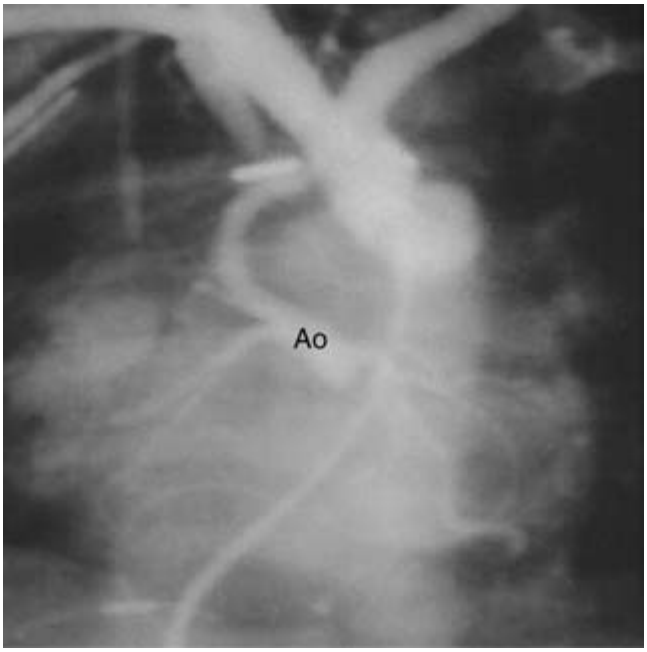

Fig. 45-4 Native aortic root (Ao) stenosis causing precoronary stenosis after the Norwood operation. The patient presented with progressive postoperative low cardiac output state with tricuspid valve regurgitation. After stabilization on ECMO and transfer to the cardiac catheterization laboratory the anastomosis was revised and the patient weaned from ECMO support. The patient has subsequently undergone Fontan operation.

Table 45-5 Principal technical complications of ECLS in congenital heart disease

Problem	Number	Percentage
Oxygenator	350	8.6
Tubing	71	1.8
Clots in circuit	646	15.5
Bleeding from surgical site	1257	30.4
Cannulae	266	6.4

Seizures	501	12.1
Renal replacement therapy	1595	37.8
Infections – blood culture positive	453	10.9
Hemolysis	335	8.1

(From ELSO Registry[000] with permission.)

Long-term outcomes

There are few data on long-term outcomes of ECLS in patients with congenital heart disease. Most studies only report survival to hospital discharge. The only published data on this topic come from Ibrahim *et al*.[59] who did a follow-up study on survivors of ECMO and LVAD from the Children's Hospital in Boston. The median follow-up time was 43 months for ECMO patients and 41 months for VAD patients. Cardiac outcomes, as assessed by NYHA classifications, showed that over 90% of patients were NYHA class I or class II. Based on assessments of cognitive function and the presence of gross motor or sensory abnormalities, 59% of ECMO and 20% of VAD patients had moderate to severe neurological abnormalities. This demonstrates that much work needs to be done on minimizing the neurological sequelae of ECLS which are probably multifactorial and include cannulation of neck vessels, heparinization and alterations in cerebral perfusion.

Summary

Mechanical support is the ultimate in high tech intensive care medicine, the outcomes from which can be truly gratifying. At the same time, it opens up a whole new era where the dividing line between what is death versus potentially survivable takes on a whole new meaning. The difficult part comes not in initiating mechanical support but in closing it down because of futility.[60] This is a concept that health care professionals and families sometimes have difficulty in accepting. Mechanical support can never be regarded as an open-ended therapy. It is now increasingly difficult to define what the indications and contraindications are in the setting of congenital heart disease.

Dilated Cardiomyopathy

Definition and diagnosis

Cardiac dysfunction and dilatation span the entire spectrum of pediatric heart disease placing its burden on both the structurally "normal" and abnormal heart of the fetus, infant, child and adolescent. Primary disease of the myocardium was first described by Krehl in 1891[1] and is distinct from the cardiomyopathies that arise from valvular, coronary, hypertensive, pericardial and congenital heart diseases. This differentiation was further emphasized by the World Hearth Organization (WHO) with the development of the Task Force on the Definition and Classification of Cardiomyopathies.[2,3] Initially, cardiomyopathies were defined as "heart muscle diseases of unknown cause." This definition was in contrast to heart muscle disease of known cause; however, this oversimplification failed to recognize not only the complex interplay between the intrinsic cardiac muscle and extrinsic factors but also that new knowledge would unveil previously undetermined etiologies. The most recent 1995 report from the WHO Task Force advocates for dual classification of cardiomyopathies by (1) the dominant pathophysiology, i.e. dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy and (2) if possible, by etiological/pathogenetic factors.[3] Dual classification provides assistance in management of patients and facilitates outcome analysis by specific subsets.

Despite heterogeneous etiologies, dilated cardiomyopathy is uniformly characterized by ventricular dilatation and impaired myocardial contractility. The ventricular wall thickness is normal or reduced, although total ventricular mass is increased. In most cases, the left ventricle is equally or more severely affected. The more unusual scenario of predominantly right ventricular dilation and dysfunction has been reported.[4] The etiology of dilated cardiomyopathy in children is multifactorial (Fig. 46-1). Known causes include familial/genetic, viral and/or immune, substrate deficiencies, toxin-induced, structural congenital heart disease and the uniquely pediatric conditions of endofibroelastosis and ventricular non-compaction (see Chapter 41G).[5,6] Schwartz *et al*. provide an excellent summary of the initial investigations of the pediatric patient presenting with cardiomyopathy.[5] Their comprehensive approach differentiates between genetic and non-genetic etiologies with particular emphasis on cardiomyopathies associated with inborn errors of metabolism, malformation syndromes and neuromuscular disorders. The identification of etiology may equip the physician to prognosticate outcome and provide appropriate genetic counseling. Most frequently, the cause is idiopathic and isolated.

In the pediatric literature, outcome reporting of dilated cardiomyopathy in children is limited to case series of small numbers. This is particularly the case in the reporting of outcomes in the so-called "dilated cardiomyopathy of known causes." This chapter concentrates on outcomes of patients with "idiopathic" dilated cardiomyopathy. The reader must however understand that included in this subset are cases which have yet to be discovered etiologies.

Historically, the diagnostic criteria for dilated cardiomyopathy included: clinical symptoms of heart failure, cardiac enlargement (on chest radiography, echocardiography, radionuclide scanning, angiography), and histopathology.[7–9] More recently, parameters have been defined to satisfy an echocardiographic definition of dilated cardiomyopathy. Echocardiographic criteria include left ventricular end dimensions two standard deviations greater than normal,[7,9–11] left ventricular shortening fractions < 25–31%[7,9–12] or ejection fractions < 35–55%.[7,10,13–16]

Histological analysis of the myocardium is critical for determination of etiology of dilated cardiomyopathy. The utility of the endomyocardial biopsy resides in the ability to assess for normal myocardium and myocarditis and to perform enzyme analysis for metabolic disturbances.[17] Better survival rates and prognosis are reported in patients with acute myocarditis as the etiology of cardiac dysfunction.[13,18] Failure to exclude myocarditis confounds interpretation of much of the pediatric literature regarding dilated cardiomyopathy. The incidence of histologically proven myocarditis among patients of all ages presenting with acute heart failure or a "dilated cardiomyopathy," varies from 4–50%.[13,19–23] Despite the very low rate of serious complications in associated endomyocardial biopsies,[24–27] histological confirmation of the absence of inflammation occurs in only 13–36% of pediatric patients in series reporting outcomes of dilated cardiomyopathy.[7–9,28–32] More recent large-scale studies in the adult population mandate exclusion of myocarditis by endomyocardial biopsies.[14,33]

In contrast to myocarditis, the histopathologic features of dilated cardiomyopathy are generally non-specific regardless of etiology and age of patient. Microscopy reveals myocyte hypertrophy with large, irregularly shaped, hyperchromatic nuclei, myofibrillary loss within the myocyte and sparse lymphocytic infiltrates. Electron microscopy also demonstrates nonspecific features of both myocyte hypertrophy and degeneration including mitochondrial hyperplasia, abnormal Z bands, dilated and disorganized sarcoplasmic and transverse tubular systems, loss of myofibrils, increased lipid droplets and glycogen, myelin figures, and increased phagolysosomes.[34]

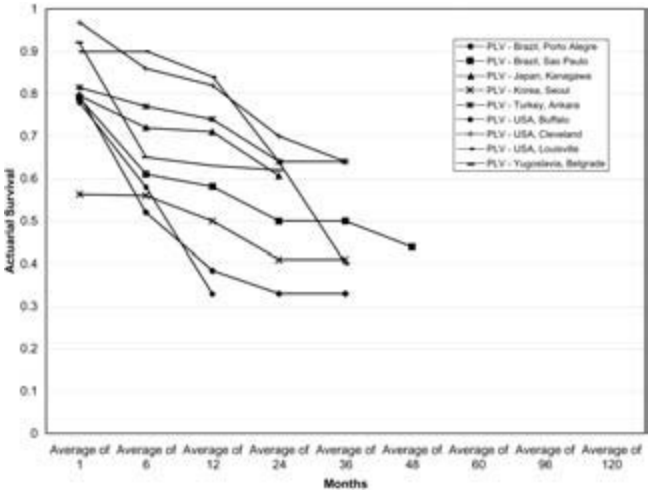

Fig. 46-1 Survival in partial left ventriculectomy series.

Incidence and prevalence

The true epidemiologic impact of dilated cardiomyopathy is unknown. It is confounded by referral patterns, ambiguities in diagnosis, and particularly by the unknown but likely substantial component of asymptomatic and undiagnosed patients.

The population-based study from Olmsted County, Minnesota, USA reports an age and sex adjusted incidence rate of 6 per 100 000 person-years.[14] Miura *et al*. report a crude incidence of 3.58 per 100 000 in the Japanese population.[35] Prevalence ranges from 14 to 43 per 100 000.[14,35–37]

Specific pediatric studies report an incidence of 0.34 per 100 000 and prevalence of 2.6 per 100 000 in the under 20-year-old Finnish population.[28] The Baltimore–Washington Infant Study reported a prevalence of 10 in 100 000 infants with cardiomyopathy.[38] Seventeen of these infants had "dilated cardiomyopathy" but included cases secondary to myocarditis, hemoglobinopathies and metabolic abnormalities.

Overall, there is a trend toward an increase in cases of dilated cardiomyopathy in the whole population likely partly attributed to improvement in case ascertainment. The Olmsted County study reported a doubling of the incidence rate between 1975–79 and 1980–84.[14]

Familial/genetic dilated cardiomyopathy

Dilated cardiomyopathy is familial in 20–35%.[11,39–42] The hypothesis that dilated cardiomyopathy is a disease of the cytoskeleton and sarcolemma ultimately leading to sarcomeric dysfunction has provided the foundation for discovery of responsible gene mutations.[43–47] Familial dilated cardiomyopathy is a heterogeneous disorder as suggested by the different patterns of inheritance: (1) the autosomal dominant pure familial dilated cardiomyopathy; (2) the autosomal dominant form in which conduction defects precede the cardiomyopathy; (3) the autosomal recessive form; (4) the X-linked form associated with mutations of genes coding for the dystrophin or tafazzin proteins; (5) mitochondrial dilated cardiomyopathy of maternal transmission; (6) right ventricular cardiomyopathy which can mimic dilated cardiomyopathy.[48]

Ten genetic loci have been mapped for the autosomal dominant pure dilated cardiomyopathy and five loci mapped for the dilated cardiomyopathy associated with cardiac conduction defects (CDDC) with identification of gene mutations of actin, desmin, δ-sarcoglycan, β-sarcoglycan, cardiac troponin T, β-myosin heavy chain and α-tropomyosin, lamin A/C proteins.[45,46] Patients with CDDC present in their twenties with mild conduction system abnormalities which may progress to complete heart block with progressive dilated cardiomyopathy.[45] Within the X-linked cardiomyopathy group, there are two well-characterized disorders. Towbin *et al.* identified the disease-causing gene, dystrophin, i.e. its severe reduction or absence in affected individuals of the X-linked cardiomyopathy (XLCM).[49,50] Affected males typically present during adolescence or young adulthood with rapidly progressive heart failure. Interestingly, despite elevations in serum creatine kinase (CK) including the muscle isoform, CK-MM, no clinical skeletal myopathy is observed.[44] Female carriers tend to develop mild to moderate dilated cardiomyopathy in their fifth decade and have slower progression. Mutations of the dystrophin gene are also responsible for Duchenne and Becker muscular dystrophies (DMD, BMD).[51] Dilated cardiomyopathy occurs in 90% of cases and is a frequent cause of mortality and skeletal myopathy is universal.[52] Barth syndrome is characterized by X-linked cardioskeletal myopathy with abnormal mitochondria, cyclic neutropenia and 3-methylglutacoic aciduria. Bione *et al.* first described the disease-causing gene G4.5 encoding the protein tafazzin.[53] Most survive infancy but dilated cardiomyopathy persists and some succumb to heart failure, sudden death or sepsis. Female carriers do not appear to develop clinical disease.[44] Dilated cardiomyopathy may be a feature of Kearns–Sayre syndrome, a mitochondrial myopathy characterized by ptosis, progressive external ophthalmoplegia, abnormal retinal pigmentation, and cardiac conduction defects.[54]

All of the genes identified for inherited dilated cardiomyopathy are also known to cause skeletal myopathy. Dystrophin mutations cause DMB and BMD, lamin A/C mutations cause Emery–Dreifuss muscular dystrophy, sarcoglycan mutations cause limb girdle muscular dystrophy and actin mutations are associated with nemaline myopathy.[43] Such associations support the hypothesis that skeletal muscle fatigue experienced by patients with dilated cardiomyopathy may be primary skeletal myopathy and not related to compromised cardiac output.

Often relatives are asymptomatic and diagnosed only by echocardiography. Except for family history, often there are no characteristics distinguishing between familial and non-familial dilated cardiomyopathy. Prospective screening revealed abnormal echocardiography in 29% asymptomatic relatives of index cases.[55] Subnormal cardiopulmonary exercise test performance in asymptomatic relatives with left ventricular enlargement but normal systolic function provides further evidence of subclinical disease.[56] Identification of affected relatives has several important implications. Monitoring may result in improved outcomes possibly through early introduction of treatment even when patients are asymptomatic. The SOLVD (Studies of Left Ventricular Dysfunction) investigators demonstrated the beneficial effects of enalapril on the reduction of heart failure symptoms and mortality in the asymptomatic patient.[57] Further, pedigree evaluation represents an essential initial step for molecular genetic studies for the identification of the disease gene.

Outcome analysis

The natural history of dilated cardiomyopathy is not completely understood. Reported outcomes vary from "full recovery" to death.[7,8,13,58] This knowledge void relates to ambiguities in epidemiologic data and heterogeneity of etiology. Asymptomatic cardiomyopathy may be present for months to years before diagnosis. Baig *et al*. report that in patients with left ventricular enlargement but normal left ventricular shortening fractions, 27% went on to develop symptomatic dilated cardiomyopathy including one sudden death and one requiring heart transplantation.[55] Mahon reported abnormal cardiopulmonary exercise tests in relatives of patients with dilated cardiomyopathy with left ventricular enlargement but normal systolic function.[56] A retrospective analysis of asymptomatic adults with idiopathic dilated cardiomyopathy demonstrated short and intermediate prognosis of 100% and 78% survival at 2 and 5 years respectively. The 7-year mortality was substantial at 53%.[16]

Adult mortality rates have demonstrated time-related improvement. One- and 5-year mortality rates of 25–31% and 50–64%, respectively, have decreased to 5–10% and 20%, respectively.[59–62] In New York Heart Association (NYHA) class IV patients, the placebo group of the CONSENSUS (Cooperative North Scandinavian Enalapril Survival Study) trial had mortality rates of 48% and 63% at 6 months and 1 year respectively.[63]

For 1978–83, 1983–87 and 1987–92, survival rates have increased from 74% to 88% to 90%, respectively, at 2 years and 54% to 72% to 83%, respectively, at 4 years.[62] This secular trend of improved survival may be related to earlier detection of disease and better medical management.

Actuarial survival analyses in children have been based on small number series all with < 100 patients and all with lack of uniformity in diagnostic criteria. There are no series in which all patients had histopathological confirmation of idiopathic dilated cardiomyopathy. Actuarial survival ranges of 41–85% and 34–80% at 1 and 5 years, respectively, were found.[7,8,12,30,64–66] Friedman *et al*. report a cumulative survival rate of 84% in 63 patients over a mean follow-up period of 4 ± 4 years[66] and Lewis reported an actuarial survival of 52% at 11.5 years in 81 patients.[29] More dismal actuarial survival was reported by Akagi *et al*. with actuarial survival rates of 54%, 41%, and 20% at 6 months, 1 year, and 3 years, respectively.[30] As in the adult population, a secular trend towards increased survival has been demonstrated. Venugopalan reported 1-year actuarial survival increasing from 69% to 85% (1980–89 compared with 1990–97).[65] Similarly, Arola demonstrated increased 1- and 5-year survivals from 48% to 70% and 42% to 52%, respectively, in 1980–85 compared with 1986–91.[28] Complete recovery of ventricular function in the pediatric population is reported in up to 25% of patients.[7,13,58]

Dilated cardiomyopathy in the fetus

Data are scant regarding assessment and outcome of fetal cardiomyopathies.[67–69] Recently, Pedra *et al*. reported 55 (8.9%) fetuses with cardiomyopathy of 612 fetuses with abnormal cardiac anatomy, rhythm, or function.[69] Dilated cardiomyopathy occurred in 22 (40%) of cardiomyopathy cases. Etiologies included familial dilated cardiomyopathy, anti-Ro or anti-La associated endofibroelastosis, intrauterine infection and idiopathic. The overall mortality in the dilated cardiomyopathy group was dismal at 82.3%, with 8 intrauterine deaths and 6 early neonatal deaths. Diastolic dysfunction in fetal cardiomyopathy is associated with the highest risk of mortality.

Congenital heart block and dilated cardiomyopathy

The incidence of isolated congenital third-degree atrioventricular block (CAVB) is reported to be 1 in 14 000 to 20 000 live births.[70] Age at presentation appears to be an important determinant in outcome.[71–74] Jaeggi *et al*. reported 102 cases of isolated CAVB in which mortality differed depending on diagnosis as a fetus, neonate (< 28 days) or child at 43%, 6% and 0%, respectively, in the first two decades of life.[73] Recent studies report a high incidence of early pacemaker intervention. Jaeggi *et al*. report Kaplan–Meier estimates of freedom from pacemaker implantation of the fetal, neonatal and childhood subgroups as 29%, 73% and 98% at 6 months.[73] Eronen *et al*. reported that 48 (53%) of newborns received pacemaker therapy within the first 3 months.[71] A subset of patients with CAVB have associated dilated cardiomyopathy that may or may not be present at time of diagnosis.[71,75,76] Incidences range from 6% to 23%.[71,72,75] Reports consistently demonstrate a strong correlation between CAVB and dilated cardiomyopathy and poor outcome. Mortality was 62% in patients with CAVB diagnosed *in utero* or as a newborn,[71] 75% when CAVB was diagnosed after 3 months of age.[72] Mortality, heart transplantation or on the waiting list for transplantation is reported to be between 75% and 89% with this association.[75,76] Possible risk factors for poorer outcomes include maternal anti-Ro and/or anti-La autoantibodies, increased heart size at initial evaluation, absence of pace-maker-associated improvement, and presence of endocardial fibroelastosis.[73,75,76]

Arrhythmias in dilated cardiomyopathy

The myopathic process of dilated cardiomyopathy manifests with clinical signs and symptoms of decreased cardiac function. Of equal prominence, the failing heart is susceptible to cardiac arrhythmias. This is a result of pathological myocyte substrate in the milieu of neurohumoral and pharmacologic triggers. In adults, conduction abnormalities occur in 80% of dilated cardiomyopathy cases and include first degree heart block, left bundle branch block, left anterior hemiblock and non-specific interventricular conduction delay.[59] Frequent and complex ventricular arrhythmias as documented on Holter monitoring are associated with an annual mortality rate of 15% with half of the deaths being sudden presumably a fatal arrhythmia.[77] Biopsies in patients with spontaneous ventricular tachycardia or fibrillation with structurally normal hearts with a mean LVEF of 65 ± 7% demonstrated abnormalities in 89%.[78] Fifty per cent were diagnosed with idiopathic dilated cardiomyopathy, 17% myocarditis, 11% arrhythmogenic right ventricular dysplasia, 11% abnormal intramyocardial arteries and 11% normal.

Specific pediatric studies addressing arrhythmia associated with dilated cardiomyopathy are scant. Similar to the adult data, arrhythmias occur frequently with electrophysiologic conduction abnormalities consisting of supraventricular and ventricular tachycardias and atrioventricular conduction block. Friedman *et al*. reported palpitations in 14% of patients and syncope or near syncope in 8 (13%) patients.[66] Arrhythmias were present in 46% of patients of which 48% were atrial in nature.[66]

Akagi *et al*. reported 52% frequency of arrhythmias in 25 patients of which 4 required a pacemaker.[30] All patients who had a pacemaker died within a mean of 12 months. Lewis and Chabot reported dysrhythmias in 24 (30%) patients.[29] Rhythm abnormalities were more prevalent in non-survivors (53% vs. 16%).

Sudden cardiac death

Adult studies report a significant proportion of sudden death in patients with dilated cardiomyopathy accounting for up to 50% of total mortality.[59,63,79–82] In the SOLVD trial, 23% of deaths were "arrhythmic without worsening congestive heart failure."[63] The V-HeFT II (Vasodilator-Heart Failure Trial II) reports 31% of deaths to be "sudden with no warning symptoms" and 43% to be "sudden with or without warning symptoms."[83] In the CHF-STAT (Congestive Heart Failure: Survival Trial of Antiarrhythmic Therapy) trial, 52% of deaths were sudden.[77,84] The mechanism of sudden death is presumed to be predominantly arrhythmia and thus may be preventable.

Predictors for sudden death include syncope, severity of left ventricular dysfunction, baseline arrhythmias and inducibility of sustained malignant arrhythmias. The V-HeFT trials found that total mortality and both pump-failure death and sudden death were related to severity of left ventricular dysfunction as measured by ejection fraction, plasma norepinephrine or peak exercise oxygen consumption.[85] The rates of sudden cardiac death (SCD) were similar in ischemic and non-ischemic dilated cardiomyopathy. Presence of ventricular arrhythmias on Holter monitoring was associated with higher overall mortality but not an increase in the proportion of sudden vs. pump-failure deaths.[79] Other studies further support the hypothesis that left ventricular dysfunction is the strongest predictor of sudden cardiac death; however, these studies of coronary patients cannot be readily extrapolated to the pediatric population.[86–90] Syncope seems to be a powerful predictor of SCD.[80,91] Middlekauff reports that, regardless of the etiology of the syncope in advanced heart failure, the actuarial incidence of sudden death by one year is 45% in patients with syncope vs. 12% in patients without syncope.[80] Inotropic therapy has consistently been associated with increased mortality almost exclusively via sudden death.[92,93]

Reduction of sudden cardiac deaths appears to be possible. The US Carvedilol Heart Failure Study Group reported a decrease in sudden death in patients treated with carvedilol (3.8% vs. 1.7%).[94] The GESICA (Grupo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina) trial reported a 27% risk reduction of sudden death in patients treated with amiodarone.[82] Comparative studies suggest superior survival with implantable cardioverter defibrillators (ICD) over drug therapy including amiodarone.[95] A primary prevention trial (Sudden Cardiac Death in Heart Failure Trial (SCD-HEFT)) comparing placebo, amiodarone and ICDs is ongoing.[79]

Patients with predominantly right ventricular dilated cardiomyopathy may represent a subset at higher risk.[4,7] Fitchett reports 5 sudden deaths in 14 patients with predominantly right ventricular dilated cardiomyopathy.[4] Of note, syncope was the initial presenting symptom in 6 patients. Arrhythmias were important in the clinical course of 12 patients.

Pediatric reports of sudden death secondary to dilated cardiomyopathy are sporadic and without exception a brief mention within case series of outcomes of dilated cardiomyopathy. Sudden death occurred in 1 of 62 patients,[7] 1 in 24 patients,[8] 1 of 25 patients,[30] 3 of 10 patients,[66] 4 of 23 patients all occurring while in hospital,[31] 7 of 63 patients,[12] 7 of 32 patients and 7 of 17 deaths.[32] Sudden cardiac death was more frequent in patients with ventricular arrhythmias on ambulatory monitoring (3 of 4 patients with ventricular arrhythmia vs. 1 of 18 patients with normal rhythm).[12]

Prognostic indicators of outcome

Ascertaining prognosis for the individual patient with dilated cardiomyopathy remains problematic. Underlying causes are important in predicting outcome yet most cases are of unknown etiology. Myocarditis and peripartum cardiomyopathy have relatively good outcomes whereas cardiomyopathy associated with infiltrative diseases, HIV infection, or doxorubicin and endofibroelastosis in children do not.[7,13,18,96,97] Grim prognosis has been reported in X-linked cardiomyopathies often with death within the first year of presentation.[98] Management of heart failure is for the most part palliative and the endpoint for many patients is heart failure related death or cardiac transplantation. A limited donor pool necessitates identifying patients whose non-transplanted mortality exceeds that associated with cardiac transplantation.

Survival during initial presentation appears to be precarious.[12,13,65] Matitiau reported that 6 of 7 deaths in children occurred < 2 months after presentation.[13] The important limitation was that this study did not histologically rule out myocarditis as an etiology. Similarly, Venugopalan reported all 12 patient deaths occurred within a year with 50% being within the first week of presentation.[65] Burch *et al*. reported 7 of 63 deaths within 3 months after presentation.[12] Further, lack of echocardiographic improvement may be associated with a higher risk of death.[12,64] Lewis reported the association of persistence (> 3 months) of left ventricular shortening fractions < 15% with poorer survival in the pediatric population.[64] One- and 5-year survival were 46% and 29%, respectively, compared with 97% and 90% respectively in the group in whom early improvement of left ventricular function was observed.

Syncope as a strong predictor of sudden death is reported in the adult population.[59] Middlekauff *et al*. reported that the actuarial incidence of sudden death by one year was significantly greater in patients with syncope (45% vs. 12%).[80] Brilakis *et al*. reported survival at 1, 2, 3, and 5 years as 81%, 74%, 69%, and 62%, respectively, in a cohort 54 patients with dilated cardiomyopathy and syncope some of whom received ICD and pacemaker therapy.[99] Fruhwald *et al*. did not demonstrate a statistically significant difference in all-cause mortality between those with or without syncope but did discover a higher rate of sudden death in the former group.[91] Pediatric studies speculate on the important role of arrhythmias in increased mortality with non-survivors having increased incidence of known rhythm abnormalities (53–71% vs. 16%).[29,32] The prognostic significance of left bundle branch block remains unclear although studies portend increased mortality (36%).[100,101]

In children, older age at presentation has been reported as a possible risk factor. Griffin identified age at presentation of > 2 years to be associated with 100% mortality during a 2-year follow-up period compared with 25% mortality in children younger than 2 years of age.[32] Similar conclusions were made by Taliercio *et al*.[8,30] To contrast, other pediatric studies have not supported this critical age of 2 years theory.[7,9,30,31,65] One must

speculate whether the higher mortality in adolescent male patients reported by Arola *et al*. reflects the undiagnosed X-linked cardiomyopathy patient subset with known grim prognosis.[7,98,102]

A number of studies show strong correlation between poor prognosis and severity of ventricular dysfunction and enlargement.[7,29,30,103–105] This has been particularly the case in the adult population post coronary infarction.[86–90] In contrast, a pediatric study of 46 patients with dilated cardiomyopathy did not identify a poorer initial shortening fraction as an indicator of adverse outcome.[106] Further, the shift of the left ventricle from an ellipsoidal to a spherical shape has been identified as a poor prognostic indicator.[13,104]

Exercise testing provides objective assessment of functional capacity in patients with heart failure and an indirect assessment of cardiovascular reserve. Its utility lies not only as a possible important prognosticator but also for objective assessment of response to therapy. Mancini *et al*. prospectively evaluated whether peak oxygen consumption during maximal exercise testing could be used to determine selection of patients in whom cardiac transplantation could be relatively safely deferred.[107] In patients in whom the maximum oxygen consumption (MVO_2) was > 14 mL/kg per min, the 1- and 2-year survival rates were 94% and 84%, respectively, vs. a 1-year survival rate of 70% in those with MVO_2 < 14 mL/kg/min. Post transplant survival at 1 and 2 years was not statistically different from those patients with MVO_2 greater than the cut-off of 14 mL/kg/min. Other studies have evaluated other MVO_2 cut-off points ranging between 10 and 18 mL/kg/min[108–110] but as Myers concludes, an optimal MVO_2 cut-off point for predicting pre-transplant survival may not exist and that peak VO_2 should be considered a continuous variable in a multivariate model to predict prognosis in severe chronic heart failure.[111] There appears to be reasonable correlation between the 6 minute walk and peak VO_2 measurements.[112,113] In recognition of the multivariate factors affecting survival, composite scores such as the prognostic score index (PSI) have been advocated.[114] This score factors the non-invasive parameters of etiology of cardiomyopathy (ischemic vs. non-ischemic), resting heart rate, left ventricular ejection fraction, mean blood pressure, peak VO_2, serum sodium and IVCD. Low risk PSI numbers had 1-year event-free survival of 93% vs. 72% and 43% in the medium and high risk groups, respectively.

Dobutamine stress echocardiography is frequently used to detect viability of myocardium in coronary artery disease. Its role in idiopathic dilated cardiomyopathy is in evolution.[101,115] Kaplan–Meier survival estimates demonstrate improved survival for patients with large inotropic responses to dobutamine (94% vs. 69%).[115] Positive response to dobutamine testing is also associated with future improvement in left ventricular function.[116] Future applications include intracoronary dobutamine infusion to assist in prognosis determination.[117]

Troponin complex on the actin filament regulates the force and velocity of muscle contraction. The subunit troponin T (TnT) anchors the troponin complex to tropomyosin. Under normal conditions, the concentration of free troponin T in the cytosol is low. Increased cytosolic concentrations reflect myocardial injury and loss of cell membrane integrity. The diagnostic and prognostic utility of TnT is extensively reported in acute coronary syndromes; however, its significance in dilated cardiomyopathy is unknown. The ongoing myocyte degeneration of dilated cardiomyopathy may be reflected in serial serum TnT measurements. Sato *et al*. reported lower survival rates in those patients with persistently elevated TnT levels suggestive of ongoing subclinical myocyte degeneration. TnT levels did not correlate with clinical presentation and appeared not to be a marker of hemodynamic decompensation but rather a manifestation of the underlying pathophysiological process.[118]

Data exist to support the negative prognosis associated with left ventricular end-diastolic pressures > 20 to 25 torr, a spherical vs. ellipsoidal left ventricular geometry, pulmonary hypertension, hyponatremia, enlarged cardiothoracic ratio on chest radiography, S3 gallop on physical examination, cardiac index < 2.5 L/min/m^2, decreased ventricular mass to volume ratio, increased levels of natriuretic factor, renin and norepinephrine.[13,29,30,59,60,109,119,120]

Treatment

Vasodilators/angiotensin converting enzyme inhibitors

Vasoconstriction in the systemic arterial and venous beds increases impedance to left ventricular ejection and shifts blood centrally from the venous capacitance vessels. The rationale for vasodilator therapy derives from efforts to decrease the preload and afterload which adversely affect left ventricular performance and contribute to the low cardiac output and venous congestion that characterize heart failure. Studies including CONSENSUS (Cooperative North Scandinavian Enalapril Survival Study), V-HeFT I, V-HeFT II, SOLVD treatment have uniequivocally demonstrated the efficacy of vasodilators including angiotensin converting enzyme (ACE) inhibitors, hydralazine and isosorbide dinitrate.[63,83,85,121]

The benefits of angiotensin converting enzyme (ACE) inhibitors in adults with dilated cardiomyopathy are undisputed through large prospective comparative trials. V-HeFT II demonstrated reduction in mortality by 28% with enalapril therapy over hydralazine and isosorbide dinitrate.[83] The SOLVD treatment trial demonstrated a 16% risk reduction in mortality and 26% risk reduction in death or hospitalization with enalapril during a average follow-up of 41 months in 2569 patients.[121] In CONSENSUS, there was a 40% reduction in crude mortality (26% vs. 44%) in NYHA class IV patients receiving enalapril.[63] The 2.5-year mortality rate in the ACE inhibitor treatment groups was *c*. 27% in SOLVD, 25% in V-HeFT II, and 36% in CHF-STAT. The Collaborative Group on ACE Inhibitor Trials reviewed the results of 7105 patients from 35 randomized, placebo-controlled trials of ACE inhibitors.[122] Overall, there were statistically significant reductions in total mortality (odds ratio [OR], 0.77) and in the combined endpoint of mortality or hospitalization for congestive heart failure (OR, 0.65). Although reductions in mortality reached statistical significance only with enalapril, similar directional benefits were observed with other ACE inhibitors (captopril, ramipril, quinapril and lisinopril). These reductions in mortality spanned across the various subgroups (age, sex, etiology, and New York Heart Association (NYHA) class). The most benefit was seen during the first 3 months of therapy and in the subgroup with the lowest ejection fraction.

Administration of ACE inhibitors has been extrapolated to children and shown similar benefits in small case series.[7,123–126] Its actions to decrease both left ventricular preload and afterload are manifested by improvement in stroke volume by *c*. 22%.[126] A retrospective comparative review of 81 patients demonstrated improved survival in the 27 children treated

with ACE inhibitors particularly during the first year after treatment.[123]

Angiotensin receptor blockers

The hemodynamic effects of angiotensin receptor antagonists (ARBs) are similar to those of ACE inhibitors but may have better tolerability particularly with the common cough side-effect (%).[127] ARBs however do not inhibit bradykinin metabolism and thus may lack this potentially beneficial vasodilatory effect. The RESOLVD (Randomized Evaluation of Strategies for Left Ventricular Dysfunction) trial demonstrated that candesartan was comparable with enalapril on exercise performance, ventricular function, NYHA functional class, and patient tolerance.[128] The combination of both drugs was more effective in prevention of left ventricular dilatation and suppression of aldosterone and B-type natriuretic peptide than either drug alone. The CHARM (Candesartan in Heart Failure – Assessment of Reduction in Mortality and morbidity) trial is ongoing comparing the addition of candesartan in patients already on ACE inhibitors with those intolerant of ACE inhibitors.[129] There are no published reports of ARBs in the pediatric population although there is anecdotal experience.

Beta-blocker therapy/carvedilol

Data support the use of β-adrenoreceptor antagonists as an adjunct to conventional therapy in an effort to slow the progression of heart failure. The negative inotropic effect of β-adrenoreceptor antagonists contraindicated its administration for many years in heart failure management. In 1975, a report from Sweden demonstrated benefits in symptoms and exercise tolerance as well as improvements in left ventricular function in patients with dilated cardiomyopathy.[130] Subsequent to this breakthrough, a number of placebo-controlled studies with various β-adrenoreceptor antagonists (metoprolol, bisoprolol, practolol, alprenolol, acebutolol, bucindolol, labetalol, carvedilol) confirmed safety of these drugs in this setting and supported further investigation.[131,132] The mechanisms of β-adrenoreceptor antagonists in heart failure are not well delineated. Unlike the selective blocking agents metoprolol and bisoprolol, carvedilol blocks both α1- and β2-adrenergic receptors. Its beneficial effects may mediate from up-regulation of cardiomyocyte β-adrenergic receptors, modulation of postreceptor inhibitory G proteins and thus ventricular remodeling, and improvement in baroreceptor function which in normal circumstances inhibits excess sympathetic outflow. Finally, its antioxidant effects may attenuate cardiomyocyte apoptosis accompanying heart failure. Large trials supporting the use of carvedilol in heart failure come primarily from the US Carvedilol Heart Failure Study Group which reported the experience of 1094 patients from 65 institutions with left ventricular ejection fraction (35% (including ischemic cardiomyopathy).[131] Follow-up ranged from 6 to 12 months. The study was terminated early on the recommendation of the Data and Safety Monitoring Board based on the finding of a significant beneficial effect on survival. The carvedilol treatment group experienced reductions in overall mortality 3.2% vs. 7.8% (risk reduction [RR], 65%), hospitalization from cardiovascular causes 20% vs. 14% (RR 27%) and combined death and hospitalization 25% vs. 16% (RR 38%). There were also improvements in the secondary end points of NYHA class and left ventricular ejection fraction. There is acknowledgement that there are some limitations in the interpretation of this study. Of cautionary note, few patients (2.9%) with NYHA class IV heart failure, were included in the study and patients hospitalized for intravenous inotropic support were excluded. Contraindications to carvedilol therapy include severe decompensated heart failure, i.e. patients likely dependent on sympathetic stimulation, marked bradycardia, sick sinus syndrome, partial or complete atrioventricular block or pre-existing liver disease. Caution is advised in patients with glucose metabolism abnormalities as signs and symptoms of hypoglycemia may be masked. The US Carvedilol Heart Failure Study Group reported a 5% carvedilol discontinuation rate from the side effects of worsening heart failure, dizziness, or bradycardia.[131]

Beta-blocker treatment for pediatric heart failure is in relative infancy with reports of small patient numbers with dilated cardiomyopathy of multiple etiologies.[106,133–137] Similar to adult management algorithms, beta-blocker therapy is initiated after patients stabilize on conventional medication regimes including angiotensin converting enzyme inhibitors.[106,134,136] Metoprolol increased shortening and ejection fractions in a multi-institutional experience of 15 children with cardiomyopathies secondary to idiopathic, anthracycline-induced, Duchenne muscular dystrophy related, postsurgical and postmyocarditis causes.[134] Four of 9 patients with idiopathic dilated cardiomyopathy increased their left ventricular ejection fraction to at least 60% after therapy (from initial ejection fractions which ranged from 21% to 46%). A multicenter report of 46 patients is the largest series of children treated with carvedilol.[106] Of the 37 patients with dilated cardiomyopathy, 24 were idiopathic. During a mean follow-up period of 13.5 months, the mean shortening fraction increased from 16% to 19% with improvements in the modified New York Heart Association class in 67%. Adverse outcomes (death, cardiac transplantation, and ventricular-assist device placement) occurred in 30% of patients. Gachara *et al*. report improvement of left ventricular ejection fraction from 25% to 39% and no mortality in 8 infants (7 with idiopathic dilated cardiomyopathy) under 24 months of age during a follow-up period of 4.5 ± 2.2 months.[135] The Toronto Hospital for Sick Children experience of 23 patients, of which 16 had idiopathic dilated cardiomyopathy, demonstrated a median improvement in left ventricular ejection fraction of 12% and median improvement in left ventricular end diastolic dimension Z-score of –1.63.[136] Kaplan–Meier analysis for freedom from death or cardiac transplantation was 91% at 2 months to 2 years. All patients were alive at a mean follow-up of 1.1 ± 0.66 years, except one patient who died post cardiac transplantation. Studies confirm the safety and efficacy of beta-blocker therapy in the pediatric population.[106,133,135,136] The discontinuation rate as a result of tolerability was between 0% and 7%.[106,134,136]

Spironolactone

Aldosterone promotes the retention of sodium, the loss of magnesium and potassium, the activation and inhibition respectively of the sympathetic and parasympathetic systems, myocardial and vascular fibrosis, baroreceptor dysfunction, direct vascular damage, and prevents the uptake of norepinephrine by the myocardium. ACE inhibition may only transiently and partially suppress the production of aldosterone.[138] RALES (Randomized Aldactone Evaluation Study) studied administration of aldactone in 1663 patients already on a baseline ACE inhibitor

therapy with left ventricular ejection fractions < 35% over a mean of 24 months.[139] It demonstrated a 30% reduction in all-cause mortality (46% vs. 35%), 35% reduction in hospitalizations and improvements in NYHA functional class in the treatment group. Most patients were in NYHA III and IV functional classes. Recommendations included consideration of aldactone for moderate to severe heart failure.

Digitalis

Drugs enhance the inotropic state of the failing heart by increases in the concentrations of intracellular sodium and cyclic AMP. Increased concentration is maintained through sodium channel agonists or through the inhibition of sodium/potassium-transporting ATPase (digitalis). Similarly, cyclic AMP synthesis is promoted through β-adrenergic agonists or by attenuating its degradation (phosphodiesterase inhibitors).

The Digitalis Investigation Group reported the effect of digoxin on 6800 patients over a 37 month follow-up period.[140] Mortality was unaffected (34.8% in placebo group, 35.1% in digoxin group). However, the digoxin group experienced 6% fewer hospitalizations particularly for worsening heart failure (26.8% vs. 34.7%, RR 0.72).

Phosphodiesterase inhibitors

Studies of cyclic AMP-enhancing agents whether the agent be a β-adrenergic agent or phosphodiesterase inhibitor all show increase in mortality.[92,93] The PROMISE (Prospective Randomized Milrinone Survival Evaluation) trial compared the impact of oral milrinone vs. placebo on 1088 patients in the NYHA functional classes III and IV over a median of 6 months.[92] The milrinone group had a 28% increase in all-cause mortality, 34% increase in cardiovascular mortality, more hospitalizations (44% vs. 39%) and more serious cardiovascular reactions including syncope. The NYHA functional class IV patients had a 53% increase in mortality. It is known that production of cyclic AMP is deficient in failing hearts[141] and that experimental animal studies demonstrate that milrinone improves the cardiac performance and survival.[142,143] The mechanism of increased mortality in humans is unknown. In rats, milrinone does not inhibit phosphodiesterase, increase cyclic AMP levels, or exert positive inotropic effects on the myocardium but appears to exert its beneficial effects primarily through vasodilation.[143] Experimental studies suggest toxic myocardial effects of cyclic AMP and enhancement of electrophysiologic mechanisms that lead to rhythm disturbances.[144–146] It is hypothesized that the decline in the production of myocardial cyclic AMP is an adaptive response to chronic heart failure and the detrimental effects of milrinone and other agents relate to their toxic effects via cyclic AMP.[146]

Thromboembolism and anticoagulation

Classic pathophysiology and biochemical studies support the clinician's suspicion of the thrombogenic milieu of the heart failure setting.[147] As such, intracardiac thrombus and embolic events, whether cerebral, systemic, pulmonary, or their combination, are well described.[7,8,30,31,41,59,65,147,148] In the adult population, prevalence estimates of thromboembolism range from 3% to 50% and incidence estimates range from 1.5 to 3.5/100 patient-years.[147] Autopsies uncovered intracardiac thrombus in 43% to 60%. Embolic events occurred in 8–16%.

Sporadic pediatric case series report intracardiac thrombus in 3 of 39 patients,[65] 3 of 13 patients,[8] 8 of 62 patients[7] and 12 (18%) of 67 patients.[149] McCrindle *et al*. reported that the left ventricular ejection fraction was not predictive of clot formation.[149] Further, thrombus formation was not significantly associated with an increase in mortality.

Vigna *et al*. reported that 8% of patients with embolism had no evidence of thrombus in the left atrium or left ventricle.[148] A left ventricular thrombus was detected in 17.5% of 80 patients. While there was 100% correlation between transthoracic (TTE) and transesophageal echocardiography (TEE) for left ventricular thrombus, TEE detected a left atrial thrombus in 18 adults who had a negative TTE, i.e. reflective of underestimation of thrombus occurrence.

There are no controlled prospective trials on the use of anticoagulation in patients with heart failure. Fuster *et al*. reported 19 embolic events during 624 patient-years in 103 patients who did not receive anticoagulation therapy (3.5 events/100 patient-years).[60] In contrast, none of 32 patients (101 patient-years) receiving warfarin therapy had an embolic event. Most larger studies failed to show a protective effect of anticoagulation with equal or higher rates of thromboembolic events in the treatment group.[83,85,150] The incidence of major hemorrhage in the adult population is between 2.3 and 6.8/100 patient-years with a suggested direct correlation with increasing age.[151] Hypothetical risk factors include severe left ventricular dysfunction, history of thromboembolism, established or paroxysmal atrial fibrillation leading to the intuitive addition of anticoagulation in heart failure management. A risk assessment including these factors might identify higher risk patients. At present, there is an absence of trial data to guide anticoagulant treatment in patients with dilated cardiomyopathy and the need for prospective trials assessing the risk–benefit ratio of antithrombotic therapy is recognized. Several trials such as Warfarin Aspirin Study in Heart Failure (WASH) and Warfarin-Antiplatelet Trial in Chronic Heart Failure (WATCH) are in progress with the hope of development of evidence-based recommendations.

Rhythm therapy in dilated cardiomyopathy

Antiarrhythmic drugs have been associated with an increase in mortality in patients with left ventricular dysfunction related to their negative inotropic and proarrhythmic effects.[152,153] Amiodarone is the only antiarrhythmic agent that is not contraindicated in heart failure associated with reduced left ventricular systolic function.[77,154–156] Amiodarone is widely believed to be effective in treating life-threatening ventricular arrhythmias; however, this conclusion is not well supported in the literature.[95,157] No randomized, placebo-controlled trials have assessed the utility of amiodarone in the prevention of recurrent sustained ventricular tachycardia or ventricular fibrillation. Amiodarone-induced suppression of ventricular premature depolarizations (VPDs) and episodes on nonsustained ventricular tachycardia (VT) is well documented.[77,158–161] In the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT), complete suppression of VPDs was achieved in 86% of the amiodarone group compared with 50% of placebo patients.[160] There are varying results regarding mortality reduction with amiodarone.[77,156] The CHF-STAT (Survival Trial

of Antiarrhythmic Therapy in Congestive Heart Failure) investigators in a randomized, double-blind, placebo-controlled trial of amiodarone in 674 patients with left ventricular ejection fractions < 40% demonstrated an increase in ejection fraction in the amiodarone group at 6, 12, and 24 months and amiodarone was significantly more effective in suppressing ventricular arrhythmias [77]. It did not reduce the incidence of sudden death. Although not statistically significant, there was a trend towards reduction in hospitalizations and cardiac death in the non-ischemic cardiomyopathy group.

The Argentinian GESICA trial demonstrated decreased mortality with amiodarone (33.5% vs. 41.4%, RR 28%).[82] There was also a 27% risk reduction of sudden cardiac death.

Resynchronization therapy

The failing dilated heart has abnormal ventricular conduction pathways as manifested by a prolonged QRS duration. Such ventricular dysynchrony may impair ejection or predispose to mitral regurgitation. Resynchronization therapy involves atrially-synchronized biventricular pacing to coordinate right and left ventricular contraction. Resynchronization therapy may be of most benefit in patients refractory to conventional medical therapy with QRS duration > 130–150 milliseconds with significant mitral regurgitation and PR prolongation.[162] The MIRACLE (Multicenter InSync Randomized Clinical Evaluation) trial was a double-blind, multi-center study of cardiac resynchronization in 228 adult patients with moderate-to-severe heart failure with QRS durations > 130 ms.[163] The primary end points of NYHA functional class, quality of life scores and 6 min walk distances were significantly better in the treatment compared with the control group. The combined risk of a major clinical event (death or hospitalization for heart failure) was 40% lower in the resynchronization group than in the control group. Of cautionary note, the follow-up period was only 6 months. Technical issues were not insignificant particularly related to the placement and maintenance of the coronary sinus pacing lead required for left ventricular pacing. Technical adverse events included coronary sinus perforation, death, or unsuccessful implantation. Other smaller series report similar successful results with resynchronization therapy.[164–167] Larger scale, longer follow-up controlled trails evaluating resynchronization therapy are in progress.[168,169]

Electrophysiologic testing

The role of programmed ventricular stimulation remains unproven. In patients with dilated cardiomyopathy without syncope, the inducibility with programmed ventricular stimulation of sustained monomorphic ventricular tachycardia ranges between 0% and 14% and of polymorphic ventricular tachycardia or ventricular fibrillation ranges between 0% and 29%.[170–177] For patients with syncope, the inducibility of ventricular tachycardia ranged from 27% to 46%.[80,99] Brilakis *et al*. demonstrated that a substantial number of patients (9 of 15) with a negative electrophysiological study eventually received an ICD.[99] Survival from the time of syncope at 1 and 3 years was 88% and 88%, respectively, for the ICD group, 86% and 76%, respectively, for the pacemaker group and 72% and 48%, respectively, for the no device group. They concluded that although electrophysiologic testing was not useful from the risk stratification perspective, it may identify other important issues such as conduction system abnormalities indicating a pacemaker.

Implantable cardiac defibrillators

Amiodarone has been adopted as the standard medical therapy for VT and VF despite scant supporting evidence. Three studies, the Canadian Implantable Defibrillator Study (CIDS),[178] Antiarrhythmics Versus Implantable Debrillators (AVID)[179] and Cardiac Arrest Study, Hamburg (CASH)[180] report improved survival with ICDs vs. anti-arrhythmic therapy including amiodarone in survivors of life-threatening ventricular arrhythmias. Meta-analysis of the three trials demonstrated a statistically significant reduction in mortality of 27% with ICDs. Amiodarone use however may continue in ICD patients to prevent ICD discharges or as primary therapy when there are economic constraints on ICD use. There is not yet a large-scale randomized study of implantable cardioverter defibrillator treatment in idiopathic dilated cardiomyopathy although studies support its use in the setting of sustained hemodynamically unstable ventricular tachycardia/fibrillation.[181] The role of ICDs in patients with LVEF ″ 35% and no record of sustained ventricular tachycardia or ventricular fibrillation is being addressed in the SCD-HEFT trial.[79]

Surgical management of dilated cardiomyopathy

Surgical therapy for dilated cardiomyopathy must be tailored to the frequently multifactorial nature of an individual patient's cardiomyopathy.[182] Until the early 1980s, "surgical therapy" was essentially limited to cardiac transplantation;[183] however, limited donor availability and the morbidity of lifelong immunosuppression have led to a search for novel treatments for dilated cardiomyopathy. Later in the 1980s, device therapy became available as bridge therapy to cardiac transplantation.[182] As experience grew treating patients with ventricular dysfunction, we learned that severe left ventricular dysfunction was not a contraindication to surgical repair. In fact, surgical therapy offered improved outcomes over medical therapy, albeit at a higher mortality. Furthermore, even though devices and transplantation were available, many patients were treated successfully without resorting to these measures.[183] Most of the published surgical work has concentrated on adults; however, pediatric data will be mentioned when available. Myocardial revascularization, device therapy, and transplantation for dilated cardiomyopathy will be covered in other chapters. Here we will concentrate on non-ischemic dilated cardiomyopathy and non-device, nonreplacement therapy.

Dynamic cardiomyoplasty

For perspective and the sake of historic completeness, dynamic cardiomyoplasty is included. In the early 1990s, a great deal of interest was generated in dynamic cardiomyoplasty. In its later development, this modality conditioned the latissimus dorsi with pacing to minimize muscle fatigue through conversion of fast twitch muscle fibers to slow twitch muscle fibers. The conditioned latissimus was then wrapped around the failing heart and paced to contract in synchrony with the heart. Recent studies have shown its effects on patient functional status in survival.[184–189]

Some investigators demonstrated improvement in functional

parameters;[189,190] however, others showed no change in ventricular function.[191] While some believed that the dynamic squeeze of the muscle wrap was important,[186,189,192–196] others came to believe that the major effect of wrapping the ventricle was prevention of further dilation and relief of cardiac wall stress.[197–199] The efficacy of this modality has been controversial in part because some studies were performed with unconditioned wraps and in others were done on normal heart, neither of which has clinical relevance. Nevertheless, this cumbersome procedure is mostly of historical interest but did form the nidus for crystallizing the newer field of passive ventricular constraining which will be discussed below.

Partial left ventriculectomy

In 1996, Randas Batista generated a new wave of interest (and publicity) with a novel surgical therapy, partial left ventriculectomy (PLV) to improve left ventricular function in end-stage heart disease.[200] The procedure was first described as excision of the lateral wall of the left ventricle between the papillary muscles. Later, Dr Batista extended the procedure to include excision of papillary muscles and mitral valve replacement (extended PLV).

Table 46-1 and Fig. 46-2 summarize the outcomes from several of the larger surgical series. This "meta-analysis" needs to be interpreted with care, because the studies were frequently designed to study different diagnostic or procedural cohorts. Some centers defined their cohort as dilated cardiomyopathy, whereas another center defined it as all patients undergoing PLV. The reader must bear in mind that even though these series are tabulated and graphed together, the outcomes from one institution are not directly comparable to another. Each study must be read in detail to understand the differences. What can be learned from the figure is the general range of survival from centers that have analyzed different cohorts of patients. In Table 46-1, care is taken to list the etiology of dilated cardiomyopathy in that table and the approach to the mitral valve, when available.

Though all the larger series are summarized, as follow-up has continued, the problem that has become apparent with PLV is that early mortality is high and that many patients have only a transient benefit, with low actuarial survival and freedom from heart failure. Sorting this out has been difficult because some studies include differing etiologies of dilated cardiomyopathy, and the surgical approach has not always been uniform, particularly with regard to mitral valve surgery. Though theories abound, the subset of patients who successfully achieve a long-lasting benefit from PLV has been difficult to identify retrospectively, and outcomes for PLV are unpredictable as a whole. Patrick McCarthy at the Cleveland Clinic has been one of the strong advocates of PLV, but at the 2002 AATS conference held in Toronto has changed his opinion based on midterm results on 62 patients with PLV in which they have come to believe that the Batista operation is not an alternative to heart transplantation because of its high risk of early failure which was largely unpredictable. The three-year actuarial survival was 53% and freedom from failure of 42%. Early and late failure precluded the use of PLV as an alternative to heart transplantation[201,202] and the procedure has been abandoned in the United States.[183]

Outcomes of PLV for dilated cardiomyopathy in children have not been reported. Anecdotal case reports of surgical success in a few children have been reported. In 1999, case reports of partial left ventriculectomy (PLV) emerged from Yugoslavia,[203] Japan,[204] and Milwaukee,[205] respectively. In Belgrade, Gradinac was the first to report a 2-year-old girl with end-stage dilated cardiomyopathy who underwent partial left ventriculectomy (PLV) and an Alfieri mitral valve repair.[203] After 1 year, her ejection fraction had improved from 19% to 34% and she was well. In Japan, an 8-month-old female with severe dilated cardiomyopathy underwent a partial left ventriculectomy and was "clinically improved" at 1 month follow-up.[204] In Wisconsin, a 3.3 kg male infant with severe dilated cardiomyopathy underwent partial left ventriculectomy and was well at 8 months of age with an ejection fraction of 50–60% and mild mitral regurgitation.[205]

Since these initial reports, four other children have been reported undergoing PLV.[206,207] Two of those required transplantation in 6 and 12 months, one of which died on postoperative day 16, and the other two were well at 18 and 35 months. In 1999, Dr del Nido[208] editorialized that dilated cardiomyopathy in children deserved special consideration, because a significant proportion of infants or children would not undergo progression and might even spontaneously recover. He argued for a coordinated multicentered effort to study patients prospectively but, to date, no such study has been forthcoming.

Mitral valve replacement

Historically, the surgical approach to mitral regurgitation was mitral valve replacement achieved by excising the mitral valve and its subvalvar apparatus. In that era, poor understanding of the relationship between ventricular function and preservation of the subvalvular mitral apparatus led to sacrifice of that apparatus and the accompanying poor outcomes.[209,210] Treating mitral regurgitation in heart failure, requires a firm understanding that the mitral subvalvular apparatus is essential to maintain ventricular function.

When looking across current series, the addition of mitral valve surgery seems to have had a positive effect on results following partial left ventriculectomy (see Table 46-2, Fig. 46-2). Independent reviews of mitral valve surgery have also shown the best survival of all. Four series of modern day mitral valve surgery in the setting of dilated cardiomyopathy have been summarized.[211–214]

Passive constraint devices

Insights learned from dynamic cardiomyoplasty stimulated the interest in passive ventricular constraint. If in fact the improvement witnessed with dynamic cardiomyoplasty was effected primarily though passive ventricular constraint then this could be much more easily achieved with a passive, non-autologous wrap. These devices have limited appeal in small children because they will, presumably, not grow (perhaps the pediatric realm is best suited to skeletal muscle wraps for this reason). Nevertheless, these modalities will be presented for the sake of completeness.

Acorn

The Acorn cardiac support device is a polyester mesh jacket which is positioned around the heart to provide diastolic support and is designed to provide flexibility and strength.[215] It is available in six sizes and is tailored to the individual heart to create a slight reduction (10% in end-diastolic dimension) in

Table 46-1 Etiologies of dilated cardiomyopathy

Idiopathic	Metabolic
FAMILIAL/GENETIC/SYNDROMIC	Nutritional
X-linked cardioskeletal myopathy (Barth syndrome)	Thiamine deficiency (Beriberi)
Noonan syndrome	Protein deficiency (Kwashiorkor)
Alstrom syndrome	Selenium deficiency
NEUROMUSCULAR DISORDERS	Beta-ketolase deficiency
Duchenne muscular dystrophy	Hypertaurinuria
Becker's muscular dystrophy	Endocrinopathies
Emery–Dreifuss muscular dystrophy	Hypothyroidism
Facioscapulohumeral muscular dystrophy	Thyrotoxicosis
Erb's limb-girdle dystrophy	Growth hormone excess
Myotonic dystrophy	Cushing's disease
Fredreich's ataxia	Pheochromocytoma
Refsum disease	Diabetes mellitus
Kugelberg myopathy	Hypoglycemia
Mini-core-multi-core Welander spinal muscular atrophy	Neuroblastoma
Nemaline myopathy	Catecholamine cardiomyopathy
Centronuclear (myotubular) myopathy	Electrolyte disturbances
Malignant hyperthermia	Hypocalcemia
Familial periodic paralysis	Hypophosphatemia
INFLAMMATORY	INBORN ERRORS OF METABOLISM
Infectious	Storage diseases
Viral	Glycogen storage disease
Rickettsial	GSD IV (Andersen disease)
Bacteria	Mucopolysaccharidoses
Myobacterial	MPS I (Hurler syndrome)
Fungal	MPS VI (Maroteaux-Lamy syndrome)
Protozoal	Sphingolipidoses
Spirochetal	Nieman-Pick disease
Non-infectious	Farber disease
Post-transplant rejection	Gaucher's disease
Collagen vascular disorders	Tay-Sach's disease
Scleroderma	Sandhoff disease (GM2)
Lupus erythematosus	GM1 gangliosidosis
Dermatomyositis	Disorders of Fatty Acid Metabolism
Myocarditis – hypersensitivity	Primary or systemic carnitine deficiency
Sarcoidosis	Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency
RHYTHM-RELATED	Disorders of diminished energy production
Congenital heart block	Kearns-Sayre syndrome
Tachyarrhythmias	Complex I deficiency
Arrhythmogenic right ventricular cardiomyopathy	MERRF syndrome
CORONARY	TOXIC
Anomalous coronary arteries	Ethanol
Kawasaki disease	Chemotherapeutic agents
CONNECTIVE TISSUE DISORDERS	Phenothiazines
Osteogenesis imperfecta	Carbon monoxide
Marfan syndrome	Lead
Pseudo-xanthoma elasticum	Cocaine
OTHER	Mercury
Endocardial fibroelastosis	Radiation
Non-compacted myocardium	
Atrio-venous malformations	
Peripartum cardiomyopathy	

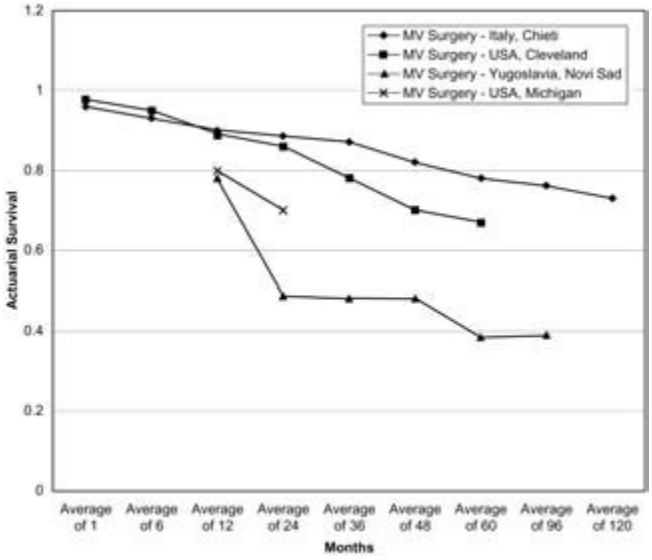

Fig. 46-2 Survival in mitral valve surgical series.

wall stress.[215] The idea of diastolic support originated from studies of dynamic cardiomyoplasty which suggested that the benefits of that procedure had more to do with the girdling effect of the latissimus dorsi than with the contractility of skeletal muscle itself.[198,199,216]

Twelve patients received the device as sole therapy, 11 with dilated cardiomyopathy. Seven were NYHA class III and 5 were NYHA class II. No intra-operative complications and no device related adverse events were reported. At 6 and 12 months there was a significant improvement in ejection fraction (from 21% to 33% to 27%) and NYHA functional class (from 2.5 to 1.6 to 1.9), and a significant decrease in both end diastolic diameter (from 74 to 64 to 64 mm), and end systolic LV diameter (from 66 to 57 to 55 mm). Mitral regurgitation diminished significantly by 3 months and quality of life improvement was present as well. No actuarial follow-up is yet available.[217]

In a second study, 5 patients with NYHA class III CHF and ischemic cardiomyopathy underwent Acorn placement in concert with coronary artery bypass grafting, +/- infarct exclusion ventricular remodeling. In this study, EF increased from 27 to 35%, LVEDD decreased from 63 to 51 mm. No early evidence of diastolic dysfunction or constriction was noted and all patients were NYHA class I at 6 months follow-up.[218]

The Acorn has had excellent outcome with no morbidity or mortality directly associated with the device. Diastolic function has not been reported and the device is currently in the second phase of PDA trials with approval at 25 US sites and an anticipated enrolment of 200 patients.

Myosplint

The Myopslint device was developed to change LV shape, decrease wall stress and improve overall LV mechanics. The device employs three ventricular splints, each attached to two epicardial pads. The splints are positioned to bisect the long axis of the LV, thereby creating two smaller ventricular cavities into a symmetric bi-lobular structure. The theory behind its design is that mural tension within each of the lobes has been decreased.[215] Chronic human studies were performed in five patients with dilated cardiomyopathy and NYHA class III. Mitral regurgitation was mild in 3 patients and moderate in 2. Four patients underwent mitral annuloplasty. In one patient, mitral regurgitation worsened necessitating Myosplint removal. In the patient who did not under go mitral annuloplasty, mitral regurgitation worsened with a decrease in LV EF from 18% to 14% and a worsened VO_2 max from 14.1 to 8.6 mL/kg/min). In the remaining 3 patients (with Myosplint and mitral annuloplasty), ejection fraction improved slightly from 23% to 25% and LV EDV decreased from 400 to 371).

The Myosplint is undergoing US FDA feasibility testing to include 20 patients from four centers as a prospective, nonrandomized, single-arm evaluation. From the early data, the role of the mitral valve and need for valvular surgery may be problematic (as it was in the early Batista experience).[215]

As is true in all of congenital heart surgery, children present unique problems with size (and the reluctance of industry to develop a range of device sizes for a small consumer base), and the need for growth (constraining the use of materials/approaches that allow for that growth). Treatment of dilated cardiomyopathy in children is still constrained by these issues. If results from adults are generalizable to children, and that is a big "if," then repairing mitral valves and perhaps the development of a passive constraint system that allows for growth are probably our best options.

Cardiac transplantation

Dilated cardiomyopathy is the most common indication for cardiac transplantation after 1 year of age.[219] Timing of listing and transplantation are of paramount concern in the setting of limited donor availability. Nield *et al*. reported a 16% waiting list mortality for 31 patients with dilated or restrictive cardiomyopathy.[220] Transplantation was achieved in 74%. The fourth official pediatric report – 2000 analyzed 4644 heart transplantations from 226 centers.[219] Actuarial survival was 80% at 1 year and nearly 70% at 5 years. The overall mortality in the first year was 50% and subsequently < 3% per year. Although > 90% of patients reported no activity limitations post transplantation, other morbidities are not uncommon including hypertension, hyperlipidemia, diabetes, malignancy, renal dysfunction and growth retardation.[219]

Novel pharmacologic treatments

As understanding of the mechanisms of cardiomyopathy and heart failure continues to grow, targeted treatment modalities are evolving. Tumor necrosis factor-(TNF-α) is a proinflammatory cytokine released from failing myocardium with high concentrations in the setting of heart failure.[221,222] Cytokine antagonists which bind irreversibly with TNF-α are currently in experimental trials (RENAISSANCE, RECOVER).[41,223,224]

A-type and B-type natriuretic peptides are released from cardiomyocytes in response to stretch and induce diuresis, vasodilation and suppression of the renin–angiotensin system. Clinical trials with exogeneous natriuretic peptides have had limited success related to tolerance. Attenuation of breakdown of endogeneous natriuretic peptides through inhibitors of neutral endopeptidases is showing more promise.[41]

Endothelins, locally acting peptides with profound vasoconstrictor effects, are found in high plasma concentrations in

patients with heart failure. Endothelin antagonists such as bosentan show preliminary favorable hemodynamic effects.[41]

Human growth hormone, acting through locally produced insulin-like growth factor 1, stimulates myocardial hypertrophy and increased myocyte contractility. Fazio *et al*. reported preliminary experience with growth hormone therapy in 7 children with moderate to severe heart failure with significant increase in ventricular wall thickness and total mass as well as improvement in ventricular function, both at rest and during exercise.[225]

Future

Early intervention

The future direction of dilated cardiomyopathy must include earlier diagnosis and treatment in the effort to modify the cellular and subsequent functional deterioraton of the cardiomyocyte. Such benefit is demonstrated in the SOLVD prevention trial which reported significantly decreased incidence of heart failure and rate of related hospitalizations in the group treated with enalapril in patients who were in NYHA class I or II with a left ventricular ejection fraction < 35%.[57]

The Pediatric Cardiomyopathy Registry

The Pediatric Cardiomyopathy Registry (PCMR), funded by the National Heart, Lung, and Blood Institute, was established in September 1995. This registry has established the largest database of sociodemographic and clinical information on children diagnosed with cardiomyopathy at 61 centers in the United States and Canada. This registry promises to provide a wealth of knowledge regarding incidence rates as well as to study the natural and modified natural history of infants, children and young adults with cardiomyopathies.

Medical management of the pediatric patient with dilated cardiomyopathy will continue to rely on extrapolations from clinical studies of adult patients. An important distinction relates to the hypothetical potential for favorable remodeling in the cardiomyocyte of the child as compared to that of the adult. As well, it appears that the etiologies of dilated cardiomyopathies in children may be substantially different from those in adults and as such mandate separate and distinct investigation. Even now, gene therapy appears to be inevitable in the future management of some forms of inherited dilated cardiomyopathy. Finally, knowledge and improved management strategies of the dilated but structurally "normal" heart may provide tremendous insight and similar applicability to the structurally abnormal heart of the pediatric patient.

Heart Transplantation

In 1966, the first human heart transplant was performed in South Africa by Barnard.[1] By the end of the 1970s, heart transplantation was established as an effective therapy for endstage heart failure. Improvements in organ donation, organ preservation, and anti-rejection therapy have resulted in improved survival rates following heart transplantation.

Incidence

It is difficult to derive true population-based data on heart transplantation. Many factors may impact whether a patient is referred and listed for heart transplantation including a wide variability in decision making around clinical need for transplantation, availability of expertise, individual center referral patterns, and medical team and familial belief systems. Therefore, the starting point for looking at natural history and outcomes is either at the point of listing for heart transplantation or once a patient undergoes a heart transplant. There are two main sources for data on outcomes related to pediatric heart transplantation: the Registry of the International Society of Heart and Lung Transplantation (ISHLT)[2] and the Pediatric Heart Transplant Study (PHTS, a research database owned and operated by the Pediatric Heart Transplant Study Group).[3]

According to the ISHLT Registry fifth annual report (2002),[2] the annual number of pediatric heart transplant procedures has remained stable since the mid-1990s as has the age distribution (Figs 47-1, 47-2). Data from the PHTS seventh summary incorporates 1586 patients listed or transplanted from January 1, 1993 to December 31, 2000 (24 centers within North America). Table 47-1 outlines the number of transplants per year over the study period with recipient age illustrated in Table 47-2. Again the number undergoing transplantation has remained relatively stable.

The diagnoses leading to transplantation are shown in Figs 47-3 to 47-5.[2] In infants < 1 year of age, congenital heart disease has remained the most common underlying diagnosis leading to heart transplantation (Fig. 47-3). Cardiomyopathy remains the main diagnosis in the 1–10 year age group, though congenital heart disease has been increasing over the last few years (Fig. 47-4). Cardiomyopathy continues to be the majority diagnosis in adolescents (Fig. 47-5).

Survival

Overall survival

Table 47-3 illustrates data from PHTS looking at survival at any time from time of listing (including deaths both before and after transplant).[3] An era effect is evident in the data with improved survival at all times post-listing in the most recent era (1997–2000).

Waiting list mortality

Waiting list mortality is an important aspect of the overall survival for heart transplantation. It is multifactorial, primarily reflecting donor availability, but also reflecting the acuity of the waiting recipients. Donor availability is difficult to influence easily, but knowledge of waiting list mortality data can often play a role in decision making around appropriate timing for listing a patient for transplant.

Data from the PHTS demonstrate a waiting list mortality in all listed patients of 12% at 1 month, 28% at 6 months, 32% at 1 year and 39% at 4 years after listing.[3] There are marked differences based on diagnosis as illustrated in Table 47-4, with the highest waiting list mortality in patients with a diagnosis of hypoplastic left heart syndrome (HLHS). Looking only at patients listed at less that 6 months of age, those with a diagnosis of HLHS still have a higher waiting list mortality at 6 months (50%) compared with infants with other diagnoses (40%) indicating that it is not just an age-related phenomenon. Clinical stability at the time of listing also affects waiting list mortality as illustrated in Table 47-5.

Survival post-transplantation

From the ISHLT Registry data, the actuarial 10 year survival for all pediatric heart transplant recipients is 55% (Fig. 47-6).[2] There is a lower survival in the infant population most notable in the first year post-transplant, reflecting the higher early mortality. However, by 10 years, the survival rate for each age group is similar, possibly reflecting a difference in the late mortality risk between the different age groups. To explore this, Fig. 47-7 shows the conditional actuarial survival after transplantation (patients surviving to 1 year, controls for the differences in early mortality). This clearly demonstrates a significant difference in late mortality between infant and childhood recipients compared with adolescents, with a yearly mortality of < 2% per year in infants and 4% per year in adolescents. Looking at it another way, infant recipients experience 40% of their mortality within the first 30 days post-transplant while adolescents experience 25% within the first month and > 50% after 1 year (Fig. 47-8).

Data from the PHTS also show that overall survival is generally good with 73% of the 1114 transplanted patients alive at 5 years post-transplant (Table 47-6).[3] Again, there are differences based on age at time of transplant with patients trans-

planted at < 1 year having a lower survival rate than older patients – likely due to the higher early mortality.

When survival data are analyzed by era, significant improvements in the results of pediatric heart transplantation are evident, with the 4 year actuarial survival for 1982–87 being 20% less than that for 1998–2001 (Fig. 47-9). The majority of improvement seems to be a decrease in the mortality within the first few months post-transplant. Looking at conditional survival again for the different age groups within the most recent era, the difference between the infants and adolescents is further accentuated with infants having a > 95% conditional 3-year survival while that of adolescents is approximately 80% (Fig. 47-10).

Pretransplant diagnosis also has an impact on post-transplant survival.[2] For patients with congenital heart disease, there is a significantly higher early mortality for infants compared with adolescents (Fig. 47-11). However, by 10 years post-transplant, the survival curves are the same. This difference does not exist for the different age groups when the diagnosis is cardiomyopathy (Fig. 47-12). Further data from the PHTS demonstrate that patients with a diagnosis of HLHS have a lower overall survival compared with other congenital etiologies, and non-congenital etiologies have the best overall survival. Risk factors for mortality

Risk factors for 1-year mortality following pediatric heart transplantation are outlined in Table 47-7.[2] The leading risk factor is a diagnosis of congenital heart disease followed by need for mechanical ventilation, diagnosis other than congenital/cardiomyopathy/retransplantation, mechanical assist devices, and donor cause of death. Table 47-8 confirms the observation that younger age is an additional risk factor. Table 47-9 lists the factors that were not significant for 1-year mortality.[2]

Clinical status at the time of transplant also affects overall survival with lower survival for sicker patients, especially for those < 6 months of age.[3] Differences in survival have also been noted when data are stratified for donor heart cold ischemic time with lower per cent survival for times of 181–300 minutes or > 300 minutes compared with < 180 minutes.[3]

Risk factors for 5-year mortality include life support at the time of transplant (odds ratio 1.93, $P < 0.0001$) and a diagnosis of congenital heart disease (odds ratios 1.64, $P = 0.001$).[2] The primary risk factors for 5-year mortality conditional on survival to 1 year is a previous transplant (odds ratio 3.39, $P = 0.02$) or inotropic support at the time of transplant (odds ratio 3.30, $P < 0.0001$).[2]

Causes of death

There were 248 deaths (22%) amongst the 1114 transplanted patients followed by the PHTS.[3] Infection, rejection, graft failure, sudden cardiac death, and coronary artery vasculopathy (CAV) are the major causes of death in children (Table 47-10).[3–5] Acute rejection also accounts for the majority of graft failure including death and retransplantation due to graft

Table 47-7 Pediatric heart transplants (1996–2001). Risk factors for 1 year mortality in descending order of magnitude ($n = 1554$)

Variable	Odds ratio	*P*-value	95% Confidence interval
Diagnosis: congenital heart disease	2.01	< 0.0001	1.44–2.80

failure.[5] Most sudden deaths are likely attributable to rejection or CAV.

Data from the ISHLT Registry also confirm the increasing mortality due to CAV to which 40% of deaths after 3 years are attributed (Fig. 47-13). Before that, acute rejection is the main cause of death – especially in the first year post-transplant (Fig. 47-14).[2]

Indications and contraindications

Indications

Indications for pediatric heart transplantation can be divided broadly into two groups: life-saving or life-enhancing. Life-saving indications include the following:

- endstage myocardial failure in the context of:
- cardiomyopathies or myocarditis
- congenital heart disease
- post-cardiotomy heart failure
- malignant arrhythmias refractory to medical or device management
- complex congenital heart disease with no options for surgical palliation at an acceptable risk
- unresectable cardiac tumours causing obstruction or ventricular dysfunction (systolic or diastolic)
- unresectable ventricular diverticula.

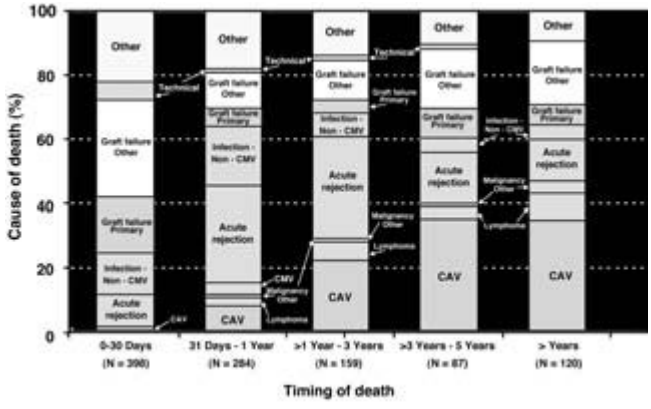

Fig. 47-13 Pediatric heart transplant recipients: Cause of death (1982–2001).

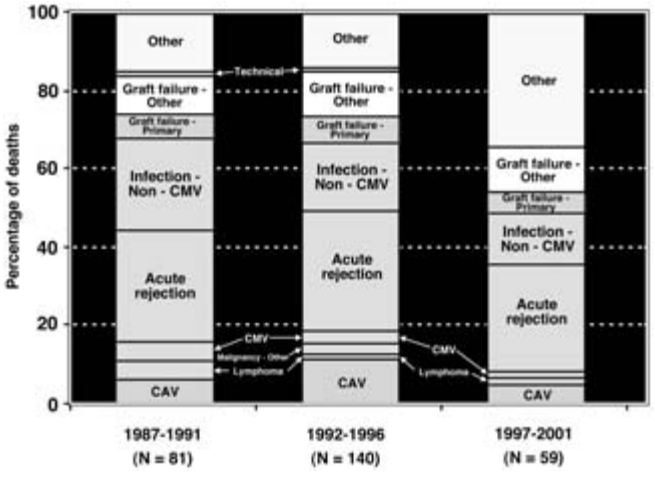

Fig. 47-14 Pediatric heart transplant recipients: Cause of death by era: deaths in 31 days to 1 year.

Life-enhancing indications include treatment of excessive disability, unacceptably poor quality of life, or long-term morbidity in the setting of failing myocardial function, complex congenital heart disease, or after failed surgical palliation of congenital heart disease.

Guidelines for listing adult patients for heart transplantation, based on a comparatively uniform population with a predictable natural history, have been published by both the American Society of Transplantation[6] and the Canadian Cardiovascular Society.[1] No such guidelines exist for the pediatric population or for adults with complex congenital heart disease. As in the adult population, criteria need to be designed to identify patients who are at the greatest risk of dying and who will derive the greatest benefit from cardiac transplantation.

If patients are old and cooperative enough for exercise testing, there are some objective data in the literature as to when heart transplantation is indicated. Although some controversy exists over the degree of impairment in exercise required to justify transplantation, in general, patients with peak oxygen consumption (VO_2) < 10 mL/kg/min should be listed for transplant.[6–11] Patients with a VO_2 > 18 mL/kg/min will experience 1-year survival rates above 95% and should be followed expectantly.[6] Management of patients with a VO_2 between 10 and 18 mL/kg/min remains controversial. A blunted systolic blood pressure (BP) response to exercise (systolic BP at peak exercise < 120 mmHg), and/or chronotropic incompetence, when associated with a VO_2 < 15 mL/kg/min or a peak VO_2 < 50% predicted help redefine the prognostic value of intermediate VO_2 values.[6,10]

Contraindications

Part of the purpose of a pretransplant assessment should be to identify factors that are potential contraindications, and to decide whether they are compelling enough to preclude candidacy for organ transplantation.

Cardiopulmonary contraindications to heart transplantation in the pediatric population included fixed pulmonary hypertension, pulmonary vein atresia or progressive stenosis, and severe hypoplasia of the branch pulmonary arteries or the thoracic aorta. Other contraindications, which can be relative, include irreversible multisystem organ failure, progressive systemic disease with early mortality, active infection, malignancy, morbid obesity, diabetes mellitus with end-organ damage, hypercoagulable states, and severe chromosomal, neurologic, or syndromic abnormalities.

Elevated pulmonary vascular resistance (PVR) is an independent risk factor for mortality both early and late after heart transplantation.[11–13] The actual degree of pulmonary hypertension precluding heart transplantation has varied as there is a continuum of increasing risk as PVR rises. Gajarski *et al.*, reported intermediate outcomes in 8 pediatric patients with PVR > 6 units m^2.[13] He concluded that it is the reactivity of the vascular bed as opposed to the absolute measure of PVR that correlated with outcome.

Complicating factors that are no longer considered contraindications to heart transplantation include complex congenital heart disease (abnormalities of situs, systemic venous abnormalities, anomalous pulmonary venous drainage without stenosis, some pulmonary artery anomalies), previous sternotomy/thoracotomy, non-fixed pulmonary hypertension, noncardiac congenital abnormalities, kyphoscoliosis with restrictive pulmonary disease, nonprogressive or slowly progressive systemic diseases with life expectancies into the third or fourth decade (genetic or metabolic cardiomyopathies), and diabetes mellitus without end-organ damage.

Risk stratification

Given the discrepancy between waiting lists and availability of donor organs, some means of assessing pretransplant risk in relation to post-transplant outcome is desirable in order to facilitate decision making concerning to whom valuable resources are allocated. We retrospectively looked at all 115 heart transplant recipients at the Hospital for Sick Children (unpublished data) and assigned them to one of three risk categories (standard, moderate, high) based on objective criteria (Table 47-11). Preliminary results demonstrated survival to 30 days post-transplant was 89%, 75%, and 42% for standard, moderate, and high risk patients, respectively. Rejection episodes were not significantly different between the high risk and the standard or moderate risk patients. Though there was a significant difference in survival for the high risk group, the reasonable percentage surviving still likely justifies continuing to transplant this population of patients.

The use of extracorporeal membrane oxygenation itself as a bridge to transplantation remains controversial given the high morbidity and mortality. Recent published experience supports reasonable and acceptable outcomes.[14,15] Looking specifically at institutional results for patients supported by extracorporeal membrane oxygenation (ECMO), there were 18 patients who underwent heart transplantation from ECMO. Median age was 6.8 years (10 days to 17 years). Mean duration of ECMO was 5.7 + 3.8 days. Median follow-up was 2.2 years (1 month to 7.2 years). Fourteen patients survived to hospital discharge. Univariate analyses of risk factors ($P < 0.05$) for poor outcome were higher creatinine before and during ECMO, significant fungal infection, and high exposure to blood products. The following did not play a role in survival to hospital discharge: original diagnosis, duration of ECMO support, wait time from listing to transplant, lactate level, cardiac arrest, indication for ECMO, site of vascular cannulation, use of ultrafiltration or bacterial infection. Patients on ECMO support may have successful outcomes despite circumstances that may previously have been considered relative contraindications (cardiac arrest, length of support, bacterial infections).

Table 47-11 Definition of pretransplant risk categories (see text)

Category	Definition
Standard	All patients not fitting criteria below
Moderate	Intubated, pulmonary hypertension, multiple or recent open heart surgery, multiple inotropes, protein losing enteropathy
High	ECMO*, sepsis, intact atrial septum in HLHS, pulmonary vein anomalies, positive PRA,† acute retransplant

*Extracorporeal membrane oxygenation.

†Panel reactive antibodies.

Neonatal advantage

There is accumulating evidence that there may be an advantage to transplanting patients in early infancy. [2,16] As outlined above, there is consistent evidence from survival curves that infants < 6 months of age have an improved long-term survival (out as far as 10 years) compared with older age groups (Figs 47-7, 47-8, 47-10). Data from Loma Linda University Medical Center have demonstrated that amongst a population of infants with HLHS, those transplanted at 1–6 months of age had a lower survival rate and higher graft loss than those transplanted at less than one month of age (Fig. 47-15). [16]

Surgical/perioperative issues

Donor issues

Donor resuscitation and support have a significant bearing on the suitability of an organ for transplantation. There is an accumulating body of knowledge on the effect of brain death on heart function and the best methods to support the circulation to preserve cardiac function for organ donation. Seemingly marginal donor organs can be made acceptable for transplantation with appropriate interventions and support with guidance from an experienced intensivist. [17–19]

The technique of donor cardiectomy is beyond the scope of this discussion but is reviewed in the surgical transplant literature. [20] Much emphasis has been placed on the method of donor organ preservation, especially cardioplegia and preservation solution, and optimal temperature for transport. Ischemic times of over 4 hours utilizing current organ preservation techniques have been shown in multi-institutional studies to be a risk factor for reduced short- and long-term survival in adult heart transplant recipients. [21] In the pediatric population, ischemic times of over 8 hours have been reported without adversely affecting short- or long-term outcomes, especially in infant donors. [22,23]

In some complex forms of congenital heart disease, there may be a need to harvest portions of branch pulmonary arteries, aorta, inferior vena cava (IVC), or the innominate vein to facilitate the anastamoses within the recipient (i.e. hypoplastic or absent central pulmonary arteries, dextrocardia with left superior vena cava, isomerism with interrupted IVC and others).

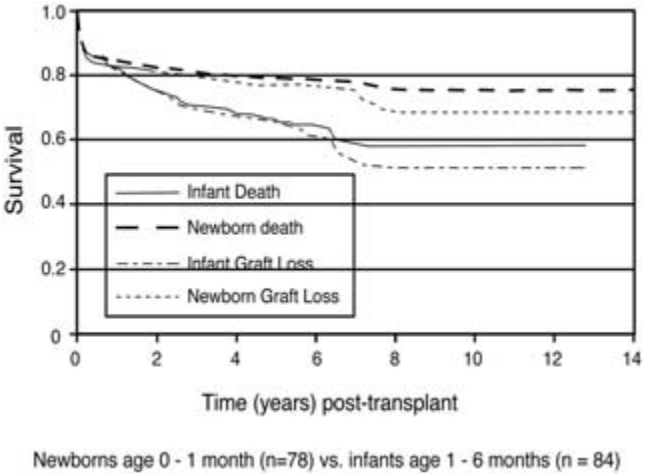

Fig. 47-15 Neonatal advantage.

Surgical techniques

There are different surgical approaches for the surgical procedure in the recipient. [24] Several retrospective studies have looked for differences in outcomes related to the type of approach. The bicaval approach, which is currently the standard in the adult population, has been described to be associated with fewer tachyarrhythmias, slightly better hemodynamics, less tricuspid regurgitation, fewer pacemakers and better exercise tolerance.[25–27] Other studies have shown no differences,[28] or only differences in the incidence of atrial tachyarrhythmias.[29] The only randomized trial demonstrated that the bicaval technique had better hemodynamics and survival.[30] The biatrial technique has been associated with conduction disturbances requiring pacemaker placement in 4–15%,[31] a higher thromboembolism risk, poor atrial synchrony, and more atrioventricular valvar regurgitation due to distortion of atrial anatomy.[32]

In summary, the preponderance of retrospective data supports a potential benefit related to the bicaval approach in adult heart transplant recipients. The most consistent finding is improved atrial function. There is fairly consistent finding that tricuspid regurgitation is decreased. There are conflicting data about the requirement for pacemaker therapy and atrial arrthymias, both short- and long-term after transplantation. However, in the pediatric population, patient size, heart location, situs, systemic venous, and pulmonary venous anatomy must all be taken into consideration when determining the surgical approach.

Recipient management

The same skills and techniques are necessary coming off cardiopulmonary bypass as in more routine cardiac operations, but there are concerns unique to the post-operative heart transplant recipient. The acutely denervated heart is frequently in a slow sinus or junctional rhythm and atrial pacing and/or isoproterenol is frequently needed. Elevated pulmonary vascular resistance with some element of right heart dysfunction is not uncommon. In addition, some degree of ventricular dysfunction as a result of ischemia-reperfusion injury (compounded by donor brain-death) can lead to acute decompensation of the transplanted heart – compounding the right ventricular dysfunction specifically. This is the life-threatening problem in the early management of these patients. There is center-to-center variability in the management of acute right heart failure. In general, maneuvers should include atrial pacing and/or isoproterenol, inotropic support, low filling pressures, avoidance of hypercapnea and acidemia, and pulmonary vasodilation with sodium nitroprusside, milrinone, phenoxybenzamine, and/or nitric oxide.

Immunologic issues

Panel reactive antibodies

Screening panel reactive antibody (PRA) testing is performed on patients before transplantation in an effort to minimize the risk of allograft rejection post-transplantation. PRA tests for the presence of preformed HLA antibodies to a random panel of donor lymphocytes. High PRA titres (> 10%) are associated with an increased incidence of rejection and reduced survival post-cardiac transplantation.[33,34] Previous open heart surgeries,

especially those necessitating the placement of homograft material, can lead to an increased incidence of elevated PRAs. There are various strategies to try to lower PRAs in sensitized patients including plasmapheresis, IVIG, cyclophosphamide, and antimetabolite treatment before transplantation.[35,36] In some high-risk cases, prospective donor/recipient crossmatching may be necessary to identify donor/recipient pairs that may be at risk of hyperacute or early vascular rejection.

ABO incompatible (ABO-I) transplantation

Heart transplantation between donors and recipients with incompatible blood groups is usually contraindicated because of the high risk of hyperacute rejection. Newborn infants do not produce isohemagglutinins and the complement system is not fully developed. West *et al*., have clearly demonstrated that heart transplantation across major blood groups is possible in the infant population and postulates that this may reflect the immaturity of the infant immune system or even represent the first human example of tolerance. [37] The obvious advantage of ABO-I transplantation is a reduction in waiting time and waiting list mortality. Whether immunologic advantages will be proven (i.e. tolerance or graft accommodation) remains to be determined.

Post-transplant issues

Post-transplant issues in the pediatric population are somewhat different than in adults. Care of children post-heart transplantation must take into consideration physical growth and multisystem development, stage of immunologic development, intellectual, emotional and social maturation, educational activities, and other pediatric quality of life parameters. Each one of these aspects and how they are considered within the management plan can affect the morbidities and mortalities post-heart transplantation. The hallmark of post-transplant care is meticulous long-term attention to details with ongoing surveillance and a high index of suspicion for transplant-related problems.

Immunosuppression

A discussion of post-transplant immunosuppressive therapy is beyond the scope of this text. However, the goal of immunosuppressive (IS) therapy is to prevent the occurrence of allograft rejection while minimizing toxicity, infectious, and malignant complications. There is ongoing controversy over what is the optimal IS regime. Overall, aim for low-intensity IS therapy that is individualized and flexible for each patient. Choice of IS therapy has significant impact on short- and long-term morbidity and mortality post-heart transplantation. There are a myriad of agents, dosages, protocols, and combinations that have been used as both induction and maintenance IS, making definitive comparisons and recommendations difficult.[2] Therapy tends to be center-specific and dependent on clinical experience and preferences of individual transplant programs.

Rejection

Rejection is the process of destruction of genetically foreign material by the host's immune system. The severity and timing depend on the degree of genetic dissimilarity between donor and recipient. Although acute graft rejection remains an important potential cause of mortality and morbidity post-transplant, its incidence and impact on graft survival have decreased over the years due to improved IS regimes. It is difficult to identify risk factors for rejection pretransplant other than sensitized patients (positive PRA).

The presence of pre-formed antibodies of the recipient to the donor graft leads to hyperacute rejection (immediate graft failure upon revascularization). Histology reveals antibody and complement deposition and polymorphonuclear lymphocyte infiltration. It can be pre-empted by antibody crossmatch and blood group matching, but cannot easily be reversed. Less than 1% of all heart grafts are lost due to hyperacute rejection.

By 6 months post-transplant, 61% of patients have had at least one episode of acute cellular rejection.[3] The majority of transplant recipients will have at least one episode of rejection in the first year post-transplant, but are usually asymptomatic and identified on routine surveillance EMB, are easily treated, and do not result in significant morbidity and mortality. Of patients alive at 1 year, 27% will experience an episode of late rejection within 3 years.[3] Mortality among patients with late rejection is significantly higher than those without late rejection.[38] Late rejection episodes are also more often associated with hemodynamic compromise requiring inotropic support. Rejection with hemodynamic compromise is associated with a higher incidence of graft failure and mortality, with only 50% of patients alive at 1 year after an episode.[39] Rejection often recurs with only 33% of patients with one episode remaining free of subsequent episodes at 5 years following the event.[40] Risk factors for rejection, late rejection, rejection with hemodynamic compromise, and recurrent rejection include older recipient age, black or Hispanic race, more frequent early rejection, greater than one episode in the first year post-transplant, and shorter time since a previous rejection episode.[38–40]

Acute graft dysfunction may occur in the absence of typical histologic features of acute cellular rejection. This is referred to as humoral or vascular rejection and is a microvascular immune-mediated injury in the absence of cellular infiltrate and necrosis. It also is a rare form of rejection and can be difficult to diagnose.[3]

Infections

Infections are an important cause of morbidity and mortality post-transplant (Table 47-10). Data from PHTS demonstrate that 40% of patients have an infection within 1 year post-transplant.[3] This number is again higher (50%) in patients who are sicker at the time of listing, especially those < 6 months of age.

A number of infections are predictable based on experience and can be managed with standard prophylactic, pre-emptive or full treatment protocols. In order to facilitate this, both donors and recipients undergo extensive screening, both serologic and otherwise, to predict potential donor organ-acquired infections that may require prophylactic or pre-emptive treatment in the highest risk time period (immediately post-transplant). Examples of this include the Epstein–Barr virus (EBV), cytomegalovirus (CMV), and toxoplasma.

Certain infections within a recipient themselves may become reactivated following introduction of immunosuppression. Again, pretransplant serologic testing would identify the possibility to heighten awareness, and routine post-transplant surveillance can sometimes allow for prophylactic or

pre-emptive treatment (EBV, CMV, hepatitis B, hepatitis C). Reactivation disease may also require treatment due to concurrent immunosuppression (i.e. varicella, shingles).

Of special mention within the pediatric population is the impact of EBV exposure given the high probability of negative exposure in the recipient. Prophylaxis is recommended for 3–4 months and surveillance should include regular testing for virus replication by polymerase chain reaction (PCR) techniques. Conversion from a negative to a positive EBV PCR requires consideration of antiviral therapy, especially in the first 6 months post-transplant. Primary infection can be severe and multisystemic, especially if within the first 3–6 months post-transplant, but the risk always exists and should be treated with antiviral therapy. Patients with a chronic viral load (persistently positive EBV PCR) should be considered for chronic antiviral therapy and regular screening for the development of post-transplant lymphoproliferative disorder (PTLD).

Most pediatric transplant recipients have not finished their routine schedule of immunizations. Titres should be checked pretransplant. Efforts should be made pretransplant to immunize with as many vaccinations as is feasibly possible and developmentally appropriate, most importantly live viral vaccines. Post-transplant, vaccination schedules should not be resumed for 6 months. Appropriate titres should be checked post-vaccination to determine response given the suppression of the immune system. Patients should never receive live viral vaccines post-transplant.

Transplant coronary artery vasculopathy

Transplant coronary artery vasculopathy (CAV) is a diffuse, chronic vascular injury to the graft. Graft ischemia results from circumferential thickening of the vascular intima (Fig. 47-16). Early clinical signs of CAV are almost non-existent in heart transplant recipients. Since the transplanted heart is denervated (i.e. not "connected") to the nervous system, the patients may not experience characteristic chest pain (angina), even in the face of significant myocardial ischemia. The diagnosis of CAV can be difficult with first clinical manifestations being symptoms of advanced disease including congestive heart failure, ventricular arrhythmias and death.

The pathogenesis of CAV is multifactorial and includes both immune- and nonimmune-related factors. It is associated with donor-specific cell-mediated alloreactivity to vascular endothelium.[41] It is promoted by a number of cytokines and growth factors.[42] There is probably some relationship between number of acute cellular rejection episodes and the risk for CAV.[43–49] Nonimmune-related associations include CMV,[50–52] possibly chlamydia,[53,54] hypercholesterolemia,[55–58] smoking,[44,47] hypertension,[44] elevated homocysteine,[59,60] elevated troponin T levels,[61] and cumulative prednisone dose.[48]

After the first year post-transplant, CAV is the commonest cause of morbidity and mortality.[2] Figure 47-17 illustrates freedom from CAV for the first 5 years post-transplant. This is highly dependent on the aggressiveness of screening and diagnosing CAV. Angiography for the diagnosis of CAV is now being questioned as the "gold standard" as it tends to underestimate CAV compared with pathology or intravascular ultrasound (Figs 47-18, 47-19).[3,62,63] In addition, angiography provides minimal information on the impact of CAV on graft function. Finally, once transplant coronary artery disease is evident angiographically, short-term mortality is high.[62,63] Supportive evi-

dence for the presence of ischemia may be obtained by exercise testing and nuclear medicine scintigraphy,[61] but the application of these testing modalities is limited to older, cooperative patients and abnormalities are manifested, if at all, at relatively advanced stages of the disease. In the youngest and smallest of patients, there may be no modality for diagnosing CAV as repetitive angiography may be technically challenging and exercise testing/nuclear medicine scans not feasible.

The use of dobutamine stress echocardiography (DSE) has been advocated in adult heart transplant recipients for routine surveillance for CAV;[64] in some centers even replacing routine angiography. Several studies carried out in adult patients now predict a relationship between an abnormal DSE and CAV-related events.[62–64] Preliminary studies in children, including one from this institution, have supported the feasibility and safety of DSE in the pediatric population, in addition to providing preliminary evidence for a role in identifying children with CAV.[65–67]

Because of the limitations of angiography, intravascular ultrasound (IVUS), has become more attractive for the identification and study of progression of CAV (Fig. 47-19). Thus far it has been used predominantly as an adjunct to angiography in the adult population.[68–70] The application of IVUS in the pediatric population is presently limited to older children due to the size of the available IVUS catheters.

Lipid-lowering therapy, specifically HMG-CoA reductase inhibitors, has been shown to play a role in the prevention of CAV. Kobashigawa *et al*. randomly assigned adult patients early post-transplant to pravastatin (n = 47) or no pravastatin (n = 50).[71] At 1 year follow-up, the use of pravastatin reduced the incidence of acute rejections associated with hemodynamic compromise, improved one year survival, and reduced the development of CAV. This was independent of cholesterol level. Therefore, the benefit of HMG-CoA reductase inhibitors goes beyond cholesterol reduction. Similar findings have been shown for a combination of low-cholesterol diet and simvastatin post-transplant.[72]

There are data in the adult literature indicating that the use of the calcium channel blocker, diltiazem, may also have a benefit in the prevention of CAV, but no long-term data are yet available.[73,74] There are very preliminary data for a role of angiotensin converting enzyme inhibitors (ACEI) in reducing vascular intimal hyperplasia.[74]

Treatment of CAV is very difficult, especially in the pediatric population. In the adult population, percutaneous transluminal angioplasty (PTCA) and/or stenting for discrete lesions has been successfully performed.[1] However, the majority of patients are not amenable to these techniques due to the diffuse nature of the disease. Similarly, coronary artery bypass grafting (CABG) has also been successfully performed in a limited number of patients, but has a very limited role.[1] An added factor for the pediatric population is that patient size often precludes

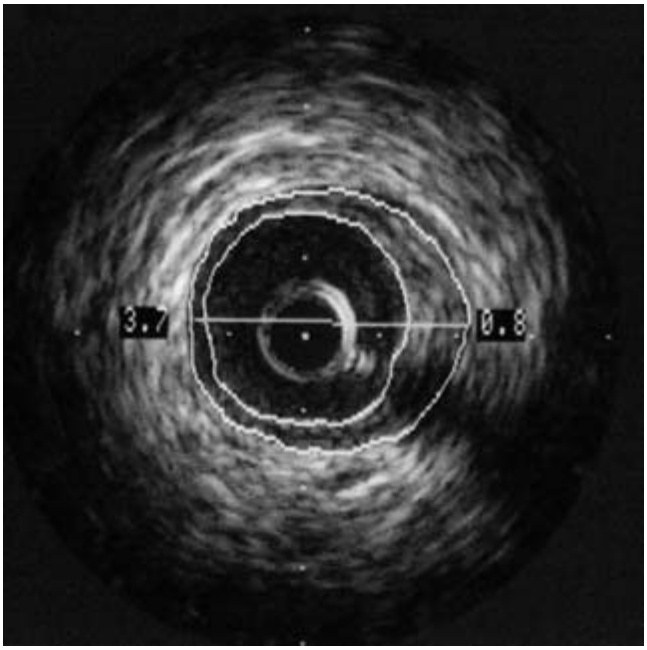

Fig. 47-19 Intravascular ultrasound of the left anterior coronary artery demonstrating intimal thickening due to transplant coronary artery vasculopathy.

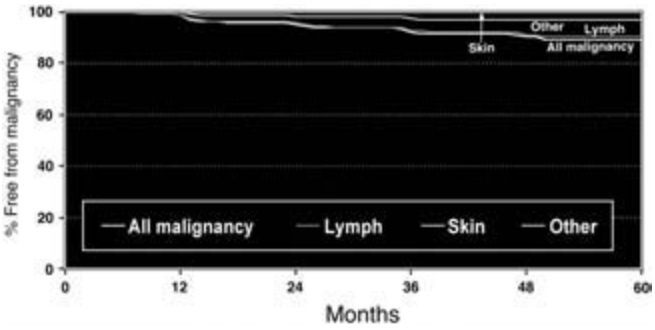

Fig. 47-20 Freedom from malignancy for pediatric heart recipients (April 1994 to December 2000).

any of these interventions. Therefore, patients with CAV may be candidates for retransplantation.

Malignancies

Malignancies are another important cause of morbidity and mortality post-transplantation. They can be *de novo*, reactivation of previous cancer, or due to chronic viral infections. The latter is the most significant in the pediatric population. Figure 47-20 illustrates freedom from malignancy for the first 5 years post-transplant, which is > 95%.[2] From the PHTS database, there were 49 malignancies in 1114 patients (0.04%), with 39 (80%) being due to post-transplant lymphoproliferative disorder (PTLD). Survival with PTLD was 95% at 1 month, 67% at 1 year, and 63% at 5 years. Again, as with any registries, these numbers are dependent on reporting, and underestimate estimates from other sources.

Post-transplant lymphoproliferative disorder (PTLD) refers to all clinical syndromes associated with lymphoproliferation post-transplant ranging from a mononucleosis-like illness to malignancies with clonal chromosomal abnormalities. EBV plays a major role in the development of PTLD with the highest risk for development being a primary EBV infection. As noted above, given the naivity of the pediatric population to EBV, primary infection and, consequently, PTLD is more common in pediatric patients. There are no controlled clinical trials comparing interventions or therapies for PTLD. The most important initial treatment is to reduce immunosuppression (or even discontinue). Antiviral medication in combination with immunoglobulin therapy is the mainstay of treatment with both acyclovir and ganciclovir having beneficial effects.[75,76] There are newer monoclonal antibodies that are showing promise.[77,78] Adjunctive therapy has included conventional chemotherapy, tumor debulking and local radiation.

Post-surgical complications

The main post-surgical complications are related to the sites of the various vascular anastamoses. Stenoses can develop at the sites of the systemic venous anastamoses (SVC/IVC), pulmonary artery anastamoses (MPA or branch PAs), or the aortic anastamosis/reconstructed aorta. These may all be amenable to intervention in the cardiac catheterization laboratory. Less commonly, the size of the left atrial anastamosis may be a problem. If it is hemodyamically significant and not recognized in the operating room at the time of the post-operative transesophageal echocardiogram, it will likely cause hemodynamic instability in the immediate post-transplant period and require a revisit to the operating room to revise. Rarely, progressive pulmonary vein stenosis can be a problem, especially if there were pulmonary venous concerns before transplant.

Other complications

Common complications that contribute to the morbidity post-transplant include hypertension, renal dysfunction, hyperlipidemia and diabetes amongst others (Table 47-12). These generally relate to the type and amount of immunosuppressive medications prescribed to the patient.

Renal dysfunction can be a significant source of morbidity in the post-transplant period. There may be antecedant compromise due to low cardiac output, chronic diuretic therapy, or mechanical support. Post-transplant, there are further insults perioperatively, and multiple nephrotoxic agents. Patients should undergo annual renal function testing including a glomerular filtration rate and screening for renal tubular acidosis. If there is renal dysfunction or it develops, kidney-sparing IS should be considered.

Osteopenia can be medically significant if it leads to osteoporosis and subsequent pathologic fractures. Many of the older patients with congenital heart disease have preexisting osteope-

Table 47-12 Post-heart transplant morbidity for pediatrics. Cumulative incidence for survivors (April 1994–December 2001)

Outcome	By 1 year		By 5 years	
Hypertension	44.2%	(n = 1507)	60.0%	(n = 365)
Renal function	(n = 1516)	(n = 389)		
Normal	94.9%	92.5%		
Renal dysfunction	3.2%	5.9%		
Creatinine > 2.5 mg/dL	3.2%	0.8%		
Chronic dialysis	1.4%	0.8%		
Renal transplant	0.0%	0.0%		
Hyperlipidemia	8.6%	(n = 1578)	17.1%	(n = 398)
Diabetes	3.2%	(n = 1509)	4.9%	(n = 366)
CAV	2.5%	(n = 1363)	11.4%	(n = 228)

nia due to lack of mobility or exercise. Screening should be done with an annual bone mineral density and prophylaxis or treatment as appropriate.

Other less medically problematic complications include hypomagnesemia and cosmetic side effects (hirsutism, gingival hyperplasia, acne, hair loss).

Growth

Growth retardation is a well-recognized morbidity in pediatric heart transplant recipients. Amongst the population followed by PHTS, growth velocity fell between the time of listing and the time of transplant. Catch-up linear growth occurred during the first year, but patients remained shorter than their age-matched peers at 6 years post-transplant. Patients transplanted for reasons other then congenital heart disease maintained steady linear growth post-transplant, but also did not achieve population means. Patients with a diagnosis of HLHS or those at a younger age at transplant showed less catch up growth.[79]

Growth data have also been analyzed in relation to steroid use post-transplant.[2] Though there were some minor differences with regards to height (linear growth) off prednisone, there did not appear to be any differences in weight gain across the age groups.

Functional status

The majority of pediatric heart transplant recipients experience excellent functional status post-transplant with > 95% reported to have no limitations at 5 years' follow-up.[2]

Strategies to improve outcomes

Donor availability

Despite improved survival, the overall number of reported pediatric heart transplant recipients remains stable, underlining an ongoing problem with donor organ availability.[2,3] There remains a worldwide gap between the supply and demand for transplantable organs which is growing. Of the patients currently on a heart transplant list in Canada, approximately 50% will never receive a transplant. In Canada in 1999, there was a 21% increase in the number of patients listed for heart transplant but only a 6% increase in the number of donors, resulting in an annual 25% mortality waiting.[1] This problem exists despite expanding acceptance criteria for donor hearts and using "marginal donors." Ongoing efforts must be made at every level of society to improve donor organ availability.

Donor

As discussed above, there is ongoing improvement and protocol development for the management of organ donors to preserve organ function following brain death. Aggressive resuscitation and stabilization using these techniques will help to facilitate more suitable potential donors and allow for improvement in the clinical status of marginal donors.

Given the data on differences in survival based on cold ischemic time, further optimization of organ preservation techniques to allow for longer cold ischemic times is warranted. This would allow for procurement of organs over greater distances, helping to increase the donor pool for any given patient.

Fetal listing

With recent advances in fetal echocardiography, more fetuses are being diagnosed with congenital heart disease at earlier stages of gestation. This has opened the door for early parental decision making regarding the possibility of heart transplantation, and has made fetal listing an option, should they wish to pursue it. Potential advantages of fetal listing include an extended time to wait for a donor organ, a favorable stage of immunologic maturation (see sections on Neonatal advantage and ABO-incompatible transplantation), avoidance of prostaglandin, inotropic or mechanical support, and limited need for risky interventions. Potential disadvantages include high pulmonary resistance with potential right heart failure in the transplanted heart, uncertainty of additional extracardiac lesions and/or undiagnosed chromosomal abnormalities, and a potential risk to the mother of an expedient delivery.

At the Hospital for Sick Children, diagnoses considered for antenatal listing include HLHS, single ventricle anatomy with risk factors for surgical palliation (severe atrioventricular valve regurgitation, decreased function), unresectable cardiac tumors, right atrial isomerism syndromes, and intractable arrhythmias. Assessment includes a detailed fetal echocardiogram for diagnosis, a detailed anatomic antenatal ultrasound for other anomalies, amniocentesis for chromosomes, and maternal blood for viral exposure and other infectious surveillance. Listing is once the fetus reaches an age of pulmonary maturity, usually at > 35 weeks gestation, and an estimated fetal weight of > 2.5 kg.

Listing criteria

As discussed under Indications, the existing stratification for listing for heart transplantation is based on a relatively predictable course of deterioration in a relatively homogeneous population with well-studied predictors of outcome. Clinical predictors of outcome are not well established for the pediatric population, especially younger patients and those with congenital heart disease. Criteria need to be designed to identify patients who are at the greatest risk of dying and who will derive the greatest benefit from cardiac transplantation. By optimizing time of listing, one would postulate that there would be some impact on early and late mortality in addition to the morbidities post-transplant.

Post-transplant care

Clearly more effective IS is needed to prevent death and graft loss following cardiac transplantation given the incidence of rejection and transplant coronary artery disease and that the major causes of death are rejection and graft failure.

Congenital Heart Block

History

Congenital heart block is a rare disorder of the fetus and newborn. It is characterized by an interruption in conduction of the cardiac rhythm from the atria to the ventricles. The natural history is well known. Congenital heart block was first reported by Morquio[1] in 1901, first confirmed electrocardiographically by Van den Heuvel in 1908,[2] defined by Yater in 1929[3] and was diagnosed antepartum in 1945 by Plant and Steven.[4]

Congenital heart block can appear in isolated or familial form, displaying a variable incidence between 1/2500 and 1/20 000 live newborns, depending on the methodology of the published studies.[5] Its diagnosis is sometimes accompanied by coexisting structural cardiopathy. In cases of normal cardiac anatomy, it is usually associated with clinical or subclinical autoimmune disease.

Evidence of association with anti-Ro/La

In 1977, McCue and colleagues described a series of 22 children with congenital complete heart block, 14 (63.6%) of which were born to 11 mothers with clinical or laboratory evidence of connective tissue disease (primarily lupus erythematosus). Seven mothers had both clinical and laboratory evidence of disease while four had only positive laboratory studies including fluorescent antinuclear antibody, rheumatoid factor, and depressed complement levels. The authors recognized that antinuclear antibodies of the IgG class cross the placental barrier and hypothesized that placental transmission of such antibodies may affect the fetal cardiac conduction system.[6] In the same year, Chameides and colleagues described six infants with congenital heart block born to mothers with systemic lupus erythematosus, and also postulated a causative relation.[7]

Neonatal lupus syndromes including congenital heart block are considered to result from a common pathogenic mechanism, the passive transfer of maternal autoantibodies. Autoantibodies such as those directed against SSA/Ro and SSB/La (proteins of the Ro ribonucleoprotein particle) gain access to the fetal circulation via the normal active transport system of the placenta before 20 weeks' gestation. An autoimmune myocarditis has been described which may be the result of these autoantibody effects on the fetal heart.[8]

In many cases, the appearance of maternal autoimmune disease may be delayed for some time.[9] In addition to systemic lupus erythematosus (SLE), Sjøgren's syndrome is also associated with congenital complete heart block. [10] The manifestation of AV block with SLE or Sjøgren's syndrome is almost uniquely a fetal disease, as adults with this disease rarely demonstrate atrioventricular block,[11] although lesser degrees of conduction system disease may occur. In 67 adults with systemic lupus, of whom 36 were anti-Ro positive, a significantly higher prevalence of myocarditis and conduction defects was found in the anti-Ro positive group.[12] However, a genetic predisposition for developing conduction system disease occurs in adults and is associated with HLA B27 with or without clinical or radiological signs of associated rheumatic disease such as ankylosing spondylitis. These include supra-Hisian second or third degree atrioventricular block, sinus node dysfunction and fascicular or bundle branch block.[13]

Serology

Antibodies to SS-A/Ro have been proposed to be a serologic marker for the neonatal lupus syndrome, which is characterized by congenital heart block, cutaneous lupus or both. The antibodies occur in the mother and are transiently found in the child's serum.[14] The relation between congenital heart block and maternal connective-tissue disease was studied by antibody screening of serum samples obtained in connection with 45 cases of isolated congenital complete heart block.[15] Serum was available from 41 mothers (17 who had connective-tissue disease and 24 who were healthy) and 21 children. Thirty-four mothers had antibody to the soluble tissue ribonucleoprotein antigen called Ro(SS-A), as identified by immunodiffusion. Anti-Ro(SS-A) was found in seven of eight serum samples collected from affected children when they were less than three months old but in none of 13 samples obtained when these children were older. It appears that maternal anti-Ro(SS-A) antibody crosses the placenta and is a marker for risk of congenital complete heart block; its absence from maternal serum suggests that a child is unlikely to be affected. Thus, anti-Ro(SS-A) or a related antibody is probably involved in the pathogenesis of congenital complete heart block.

Ro(SS-A) autoantibodies are found in the majority of the cases of "idiopathic" CHB, are of maternal origin, and constitute a marker for the syndrome. When pregnancies with echocardiographically confirmed, isolated congenital heart block were assessed, all mothers had evidence of circulating anti-Ro antibody.[16] In the study of Taylor and colleagues, 35/35 mothers of babies with congenital heart block had either Ro (SS-A) or La (SS-B) antibodies, compared to 0/5 mothers of babies with other types of heart block, 10/29 women with connective tissue disease without babies with heart block, 4/445 normal pregnant women and 2/109 healthy nonpregnant women. Of 15 babies

with congenital heart block, 10 of 10 who were < 3 months old possessed antibody. Antibody titres in affected but not in normal infants were lower compared with their mothers' titres, suggesting deposition of antibodies in the baby's tissues.[17] A reduction in anti-Ro (SS-A) binding in the affected newborn of a twin pregnancy suggests that anti-Ro antibodies are consumed and thus intrinsically involved in the pathogenesis of the disease.[18] However, not all infants of SS-A antibody positive mothers are affected.[19]

In a study by Buyon *et al.*, antibodies specific for one or more components of the Ro/ribonucleoprotein particle were found in sera from all 20 mothers of permanently affected infants. However, no antibody specific for a single peptide of this particle was common to all sera. The predominant antibody response in the NLE group was to the newly recognized 52-kDa SSA/Ro peptide component (in contrast to 60-kDa SSA/Ro). Antibodies directed against the 48-kDa SSB/La antigen were demonstrated in 90% of NLE mothers, often accompanying antibodies against the 52-kDa SSA/Ro component. The combination of antibodies to 48- and 52-kDa structures was significantly increased in the NLE group, with an odds ratio of 35:1.[20] In another study, the odds of giving birth to a child with CHB were increased by a factor of 22 for women with antibodies to Ro(SS-A) and/or La(SS-B) compared with women who did not have these antibodies.[21] However, anti-52 kDa Ro antibody levels in mothers of children with congenital heart block did not differ from anti-Ro/SS-A positive mothers of healthy children[22] Specific antibody profiles do not distinguish among the manifestations of the neonatal lupus syndromes.[23] Although there is no unique antibody profile specific for CHB, mothers with a high or low risk of having a child with CHB can be identified.[24] Reichlin and colleagues assessed eluates from the heart of a child who had succumbed to CHB and suggested that anti-native 60-kDa Ro/SS-A may have a major role in the immunopathogenesis of CCHB.[25] Silverman and colleagues assessed antibody titres against recombinant 52 kD Ro protein and peptide fragments (fine specificity) of the La protein and suggested that the autoantibody response to the Ro/La particle can differentiate sera from mothers of children with NLE and sera from mothers of unaffected children.[26] Autoantibody levels and fine specificities appeared to fluctuate with time, a finding that has been contradicted by others.[27] Anti-calreticulin antibodies have also been identified as markers for CCHB. Calreticulin is involved in calcium storage and therefore anti-calreticulin antibodies might influence the development of CCHB.[28] However, there is still no definitive test to determine prospectively which babies will be affected. Treatment during gestation is still controversial and, if attempted, should be reserved for fetuses with potentially life-threatening disease.[29]

The cellular target of autoantibodies in CCHB has also been the subject of much work. Antibodies raised against maternal anti-La antibodies react strongly with the surface immunoglobulin on the myocardial fibres from a CCHB heart but not those of a control fetal heart. Both La and Ro antigens can be identified on the surface of affected heart muscle cells, in addition to complement. This suggests that induction of Ro and La antigens on the surface of myocardial fibres during fetal development may be critical in the localization of the specific autoantibodies and subsequent evolution of congenital complete heart block.[30]

Mothers who have one child affected are at risk for having a second child affected, but are often asymptomatic. Autoantibodies reactive with fetal heart tissue are present in a higher proportion of mothers of infants with CCHB, but these antibodies may not react selectively with the conduction tissue. It has been suggested that a second factor is necessary to induce the condition.[31] HLA associations in this syndrome are HLA-DR3, HLA-B8, HLA-MB2, and HLA-MT2, and these occur in mothers but not infants.[32–35] Maternal DR3 and Ro antibody seem to be independent factors associated with CCHB.[36] CCHB does not appear to be related to a specific HLA pattern in affected children,[37] although some family studies suggest otherwise.[38]

CCHB in twin pregnancies

Neonatal lupus erythematosus may occur in only one fraternal twin. The presence of circulating antibodies in the unaffected twin suggests that the anti-Ro antibody is a necessary but not sufficient factor for the occurrence of tissue injury in children with neonatal lupus erythematosus. HLA determinants were suggested to be involved in the expression of disease in neonates who have been exposed to the anti-Ro antibody,[39] but the presence of discordant outcomes in identical twins would not be in keeping with this.[40] Placental transfer of anti-Ro(SSA) or anti-La(SSB) alone to the fetus is not sufficient for the expression of congenital complete heart block. There must be a second event determining which infant develops complete heart block, but this is unknown at present.[41] An alternative explanation is that anti-La antibodies cross-react with laminin in the placenta, possibly preventing the majority of potentially pathogenic antibodies from reaching the fetal circulation.[42]

Pathology

The pathology of the conduction system in congenital complete heart block has been described by a number of investigators including Lev, Bharati, Anderson, Ho, James and others.[43] The A-V node is often isolated by collagen at all its margins except at the junction with the His bundle.[44] The anticipated area of the atrioventricular node may be occupied by fibrous and adipose tissue, and the sinus node may also show hypoplasia.[45] Hearts of patients with CCHB have absence of the approaches to atrioventricular node, as well as having partial or complete absence of the AVN.[46] In the evaluation of a fetal death, subacute myocarditis has been associated with microcalcifications of the conductive tissue.[47] IgG deposition has been reported in the conduction system of hearts of babies who died from heart block.[48,49] Small infiltrates of mononuclear cells and limited, patchy deposition of complement were also observed.[48] Alternately, immune-triggered apoptosis (programmed cell death) is another possible explanation for the pathogenesis of CCHB.[50]

Pathophysiology (Fig. 48–1)

The pathophysiology of CCHB remains unclear. National registries have been established in the US and Canada.[51] Assays for anti-Ro (SSA) and anti-La (SSB) antibodies should be performed on sera of pregnant women with SLE and newborns with CCHB.[52] Data from the NIH registry substantiate that autoantibody-associated CHB carries a substantial mortality in the neonatal period and frequently requires pacing. The recurrence rate of CHB is at least two- to threefold higher than the

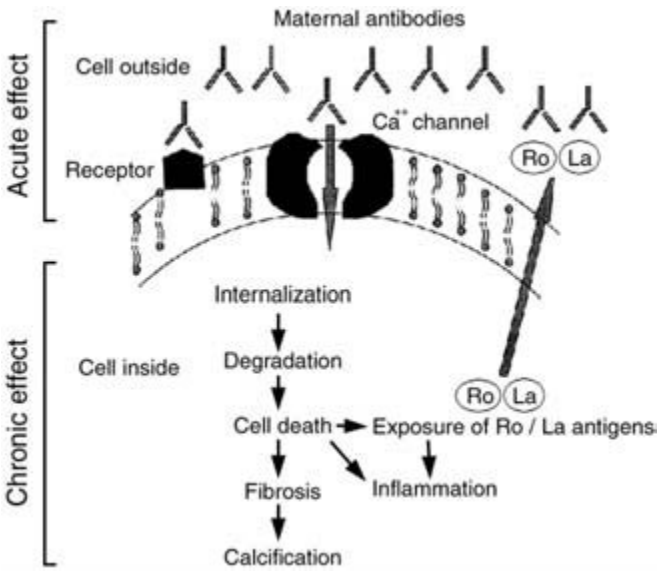

Fig. 48-1 Hypothesis of the pathophysiology of congenital complete heart block. Maternal autoantibodies may cross-react and target the neonatal calcium channel or an associated receptor. The associated alterations in Ca^{++} flux may trigger cellular events which increase the surface expression of autoantigens. Surface expression of autoantigens directs additional immune-mediated injury. (From Boutjdir *et al*.[50A] with permission.)

rate for a mother with anti-SSA/Ro-SSB/La antibodies who never had an affected child, supporting close echocardiographic monitoring in all subsequent pregnancies, with heightened surveillance between 18 and 24 weeks of gestation.[53]

Clinical presentations

Frohn-Mulder suggested that two types of heart block can be recognized. Typical congenital heart block is associated with maternal anti-Ro/SS-A antibodies and numerous obstetric and neonatal complications, but heart block that is identified later in life is rarely associated with maternal autoimmunity and has a lower risk for recurrence.[54] Patients occasionally present with lesser degrees of AV block.[55–57]

The radiologic manifestations of complete AV block, although not specific, have been described in detail and include simulated shunt vascularity, pulmonary venous hypertension, redistribution of blood flow to the upper lungs, cardiomegaly and variation in cardiac size on serial examinations.[58] Heart size is reduced significantly after pacemaker implantation.[59]

Levy and colleagues monitored 20 patients with congenital complete heart block (CHB) with ECG tape recordings while awake and asleep. Episodes of marked ventricular slowing during sleep (pauses > 3 s) were noted in 35%.[60]

Cecconi and colleagues followed 38 patients with detailed evaluation and follow-up. Twenty-two patients were asymptomatic, and 16 had symptoms such as syncope or presyncope, marked exercise intolerance, presyncope and marked exercise intolerance, heart failure or mild dyspnea on exertion. Electrocardiograms showed a narrow QRS in all patients. Holter monitoring showed a marked bradycardia (awake heart rate ″ 55 beats/min in infants, ″ 40 beats/min in children and adults) in 15 patients and junctional pauses of > 3 s in 9 of them. The exercise test showed a markedly reduced exercise tolerance in 2 patients and exercise-induced complex ventricular arrhythmias in 3 patients. Echocardiography showed a structurally normal heart and a normal left ventricular function in all patients. The electrophysiologic study always showed a supra-Hisian site of block.[61]

Fetal diagnosis

Antenatal diagnosis has been reported for many years.[62–64] Fetal electrocardiography has been used to confirm the diagnosis,[65,66] but M-mode and real-time two-dimensional echocardiographic studies have become the standard for diagnosis.[67,68] Echocardiographic assessment of the heart can give an accurate prognosis in fetal bradycardia and provide a basis for appropriate obstetric management. Isolated complete heart block often has a good prognosis if the pregnancy is carefully managed.[69] Hydrops fetalis may complicate the neonatal presentation,[70,71] but is much more common in patients with heart block and structurally abnormal hearts,[72–74] as is neonatal death.[75] The detection of congenital complete heart block (CCHB) in a fetus should alert the obstetrician that the welfare of both the mother and the newborn infant may be in jeopardy. An awareness of this uncommon cause of fetal bradycardia and judicious intrapartum monitoring can avert hasty and unnecessary cesarean section for suspected fetal asphyxia.[76] However, when this inadvertently occurs, a staged approach to pacing can be initiated.[77] On the other hand, close evaluation may identify the fetus at risk where delivery may be beneficial.[78] Habitual fetal loss is also an occasional complication of maternal SLE in pregnancy, and it is as yet unclear to what extent fetal heart block or other mechanisms contribute to this loss.[79,80] In one series of children with CCHB, the mothers did not have an increased risk for spontaneous abortions.[81] However, in other studies, combined fetal and newborn loss related to congenital heart block is reported to be as high as 50%.[82,83] An individual heart rate does not necessarily predict the outcome *in utero* or the need for postnatal pacing.[84]

Heart block and the QT interval

An association of QT interval prolongation with congenital heart block has been recognized,[85] with approximately 25% of patients demonstrating some QT prolongation.[86] This association is separate from the entity of 2:1 AV block which occurs due to ventricular refractoriness in congenital long QT patients with marked prolongation of the QT interval.

Clinical outcomes

Adults with CCHB may have associated findings of mitral valve prolapse.[87] Endocardial fibroelastosis is a recognized association with congenital complete heart block,[88] and can occur in a concordant fashion in twins with congenital complete heart block.[89] It can also occur in anti-Ro antibody-exposed pregnancies in the absence of complete heart block.[90]

The prognosis of congenital complete atrioventricular block (CCHB) is usually considered favorable in adults. This belief is based on studies comprising a limited number of patients and with rather short observation times. The natural history of the disease has been investigated by a prospective follow-up

through several decades of adult life of patients with a large group having well-defined CCHB without structural heart disease. Prophylactic PM treatment was recommended even for symptom-free adults with CCHB because of the high incidence of unpredictable Stokes–Adams attacks with considerable mortality from first attacks, a gradually decreasing VR, significant morbidity, and a high incidence of "acquired" mitral insufficiency.[91]

We reviewed our institution's experience with isolated congenital heart block (CAVB) to identify pre- and postnatal predictors of mortality and the requirement for pacemakers in infancy and childhood. The medical records of all cases encountered at our institution from 1965 to 1998 were analyzed. Of 102 cases identified, 29 were diagnosed *in utero* at an average of 26 weeks' gestation, 33 as neonates and 40 as children at an average age of 5.7 years. (Fig. 48-2) Maternal anti-Ro and/or anti-La antibodies were present in 95% of fetal and 90% of neonatal cases, but only in only 5% of mothers of older children. Mortality in the three groups was 43%, 6%, and 0%, respectively (Fig. 48-3) Increased mortality risk was associated with a fetal diagnosis of complete heart block (13/15 deaths), fetal hydrops (6/6 cases), endocardial fibroelastosis (5/5 cases) and delivery at < 32 weeks (4/6 cases). Timing of pacemaker implantation differed significantly among fetal vs. neonatal and neonatal vs. childhood cases. At 20 years of age only 11% and 12% of CAVB patients with neonatal and childhood diagnosis, respectively, were not paced (Fig 48-4).[92]

Maternal outcomes

The development of rheumatic disease in asymptomatic mothers identified by the birth of a child with congenital heart block is common but not universal.[93] The long-term outcome for the mothers of children with CCHB is more reassuring than generally assumed.[94] In the experience of Press and colleagues, 25% of the mothers with an undifferentiated auto-immune syndrome and only 2% of the initially healthy mothers developed SLE.[95]

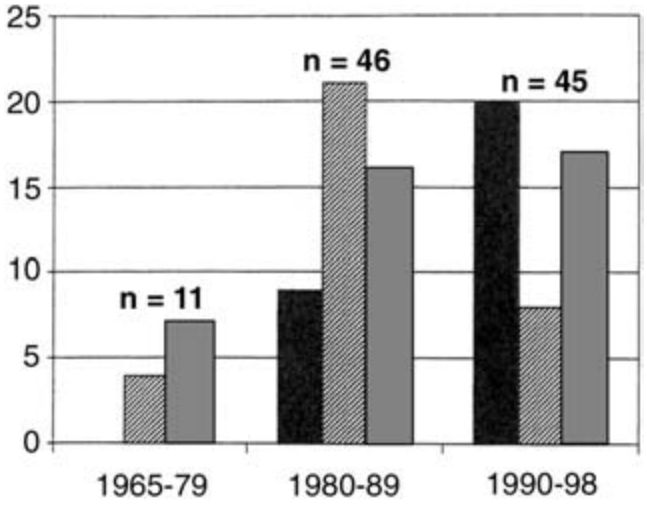

Fig. 48-2 Fetal, neonatal or childhood presentation of congenital heart block vs. era fetal presentation (solid bars) increased significantly during our experience compared to neonatal (hatched bars) and childhood presentations (grey bars). Natural history

"Unaffected" infants may have somewhat longer PR intervals, but still within normal range.[96] Occasionally, patients will present with lesser degrees of AV block.[97]

Although return of A-V conduction has been described in rare patients after long periods of high-grade or complete congenital heart block,[98,99] it remains unclear whether this disorder is truly reversible.

Newborns with CCHB have had a neonatal mortality rate of up to 20% without treatment.[100] and as high as 15–16% even with treatment.[101,102] Congenital complete heart block may be associated with fatal Stokes–Adams attacks later in life as well.[103,104] The mortality is highest in the neonatal period, much lower during childhood and adolescence and increases slowly later in life.[105] Most patients who survive beyond infancy are able to lead relatively normal lives.[106]

In Cecconi's study, 20 patients (53%) underwent cardiac pacing at a median age of 14 ± 10 years and were followed up for 110 ± 59 months (range 18–253) after pacing; prophylactic pacing was performed in 10 patients.[61] Indications for cardiac pacing were: syncope or presyncope (7 patients), presyncope and marked exercise intolerance (1 patient), neonatal heart failure (1 patient), marked exercise intolerance (1 patient), neonatal marked bradycardia (2 patients), marked bradycardia with junctional pauses of > 3 s and/or complex ventricular arrhythmias (7 patients) or complex ventricular arrhythmias (1 patient). No death occurred during the follow-up. In 9 of 20 patients who had cardiac pacing, indication for this procedure appeared during the follow-up (development of symptoms, marked bradycardia and/or complex ventricular arrhythmias). Complications of pacing were infrequent (9 complications in 7 patients). All patients who had pacing showed an improvement of exercise tolerance; 11 of them underwent exercise test after pacing which showed a significant increase in exercise duration. In the 3 patients with complex ventricular

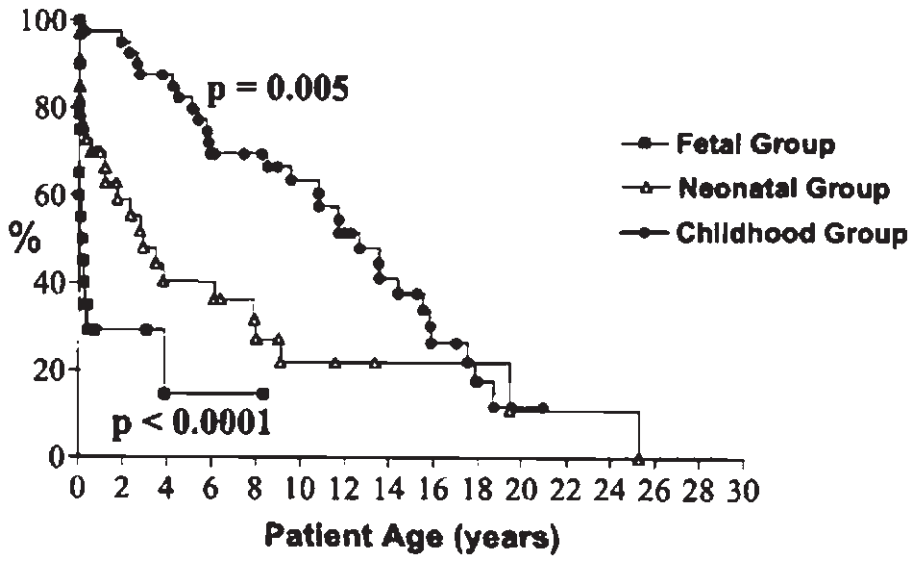

Fig 48-4 Kaplan–Meier freedom of pacemaker implantation comparing fetal, neonatal and childhood diagnosis of CAVB. Global differences between the groups (log-rank; 2 = 28.4, $P < 0.001$) were further analyzed using log-rank tests and Bonferroni corrections. Time of implantation differed significantly between the childhood group and the neonatal group (2 = 7.8, $P = 0.02$) and between the childhood group and the fetal group (2 = 33.9, $P < 0.001$) but not between the neonatal and fetal groups (2 = 4.4, $P = 0.09$) after adjustment for multiple comparison. (From Jaeggi *et al.*[92] with permission.)

arrhythmias, they observed suppression after atrioventricular sequential pacing.

Prediction of syncope (Stokes–Adams attacks)

Stokes–Adams attack is a historical description for sudden cardiovascular syncope associated with bradycardia.[107] Congenital heart block can be associated with fatal Stokes–Adams attacks.[108] More typically, Stokes–Adams attacks occur without major sequelae and initiate the placement of a permanent pacing system.[109] Stoermer and Schramm recognized that patients with congenital heart block usually had faster, narrow-complex escape rhythms and a good prognosis compared to other patients with AV block, but that most would eventually require pacemaker implant.

Karpawich and colleagues provided the first detailed assessment of risk factors for (potentially fatal) Adams–Stokes attacks in the patient with congenital heart block. Twenty-four children with congenital complete AV block were followed up for 1–19 years. One or more Adams–Stokes episodes were experienced by 8 children, 1 of whom died. Only a persistent heart rate at rest of 50 beats/min or less demonstrated a significant correlation with the incidence of syncope. Intracardiac electrophysiologic study was of little benefit because site of block did not correlate with syncope. Ventricular pacemakers were implanted in 10 children. Each child was asymptomatic over a 1- to 10-year follow-up period.[110]

Dewey and colleagues followed 27 patients prospectively with Holter monitors for a mean of 8 years. Eight of 13 patients with a mean daytime heart rate below 50 beats/min (group A) had cardiac complications such as sudden death, syncope, presyncope, or excessive fatigue. Six of the 8 also had junctional instability. None of the 14 patients with a mean daytime heart rate of 50 beats/min or more (group B) had an adverse clinical outcome.[111]

The reports of Dewey and Karpawich did not study patients with isolated CHB exclusively, but included patients with congenital heart block in the face of structural heart disease. Nagashima and colleagues studied a small group of patients with isolated CHB, and considered junctional exit block as a possible risk factor.[112] A prolonged RR interval > 3 s is now accepted as a risk factor.[112] Other identified risk factors for syncope include ventricular ectopy and poor chronotropic response to exercise,[111] More recently, Michaelsson and colleagues demonstrated that such risk factors do not always predict Stokes–Adams attacks (even fatal ones) in adults,[91] and suggested that all patients over age 15 years with congenital heart block receive permanent pacemakers.[113]

In 5 subjects with congenital complete A-V block, the site of block as determined by invasive electrophysiologic study could not be predicted from the surface ECG.[114] Certainly, the block is supra-Hisian in the majority of patients.[115]

Subsidiary ventricular pacemaker function was evaluated in 20 children with congenital or surgically induced complete heart block, and long-term ECG tape recordings were performed in eight of these children. His bundle recordings showed that the site of block did not allow separation of patients with symptoms from those without symptoms. Prolonged recovery times were present in patients with block above the His bundle recording site who had symptoms of syncope or dizziness, as well as in patients who had a wide QRS. However, some asymptomatic patients with heart block above the His bundle recording site also had long recovery times.[116]

A fixed or decreasing low ventricular rate neonatally and a prolonged QT time seem to be bad prognostic signs.[105] QT prolongation in congenital complete heart block may be associated with episodes of torsade de pointes[117] which may occur even late in life.[118,119] Symptoms in early infancy were a more serious risk factor in the experience of Reid and colleagues.[104] Patients who developed ventricular ectopics with exercise had lesser increments in their junctional rates with exercise and were more likely to subsequently experience syncope and require pacemaker insertion.[120]

Sholler and Walsh found that heart rate on electrocardiogram or Holter monitor did not clearly distinguish a subgroup at risk. The presence of alternate "risk factors," such as atrial enlargement seen on electrocardiogram, cardiomegaly seen on X-ray film, a prolonged QT interval or ventricular ectopy on Holter monitoring were independent predictors of symptoms and poor outcome.[121]

Normand and colleagues assessed for the presence of syncope, cardiac failure, low heart rate, increased QRS duration, prolonged QTc, infrahisian AVB, long pauses or arrhythmias on Holter monitoring as indications for pacemaker therapy. The only significant prognostic factors in this series were a previous history of syncope, increased QRS duration and a QTc of > 0.45 s.[122]

Michaelsson and colleagues provided an update of their studies on the natural history of congenital complete AV block. A risk for heart failure, syncope, and sudden death is present at any age including fetal life. Unfavorable prognostic signs *in utero* are low and include decreasing ventricular rate, hydrops, AV valve regurgitation, and low aortic flow velocity. Indications for pacing in infancy are congestive heart failure, ventricular rate < 55 beats/min in isolated block and < 65 beats/min with associated disease, prolonged QTc, syncope attacks, frequent ventricular ectopic beats, and alternating ventricular pacemakers. Indications for immediate pacing in childhood and adult life are syncope, presyncope, low ventricular rates, periods of junctional exit block, prolongation of QTc and mitral regurgitation. Pacing is recommended to all patients older than 15 years.[113]

Exercise tolerance

Patients with congenital complete heart block can adapt to exercise through an increase in ventricular rate (from a mean resting rate of 50 beats/min to a mean exercise rate of 112 beats/min), an increase in stroke volume, or (to a lesser degree) an increase in venous oxygen extraction.[123] In most patients with CCAVB, the LV was enlarged with normal geometry and enhanced systolic function during the first two decades of life.[124] Resting cardiac output is maintained at a normal level by an increase in end-diastolic volume, but no appreciable change in the end-diastolic volume occurs during exercise.[125] However, 68% (17/25) of heart block patients have significant ventricular ectopy (frequent unifocal ectopy or worse) on exercise. There is a significant trend toward more frequent and more severe ectopy with increasing age and also in patients with QRS prolongation.[126]

In patients with congenital complete atrioventricular (AV) block, treadmill exercise testing demonstrated a significantly lower ventilatory threshold than normal. There was an inadequate hemodynamic adjustment to the relative exercise bradycardia and a higher than normal anaerobic/aerobic energy supply. The resting heart rate did not predict either exercise bradycardia or the degree of exercise intolerance.[127]

Therapy

Fetal therapy

Early corticosteroid treatment of the mother's disease had no beneficial effect on AVB in the fetuses reported by Herreman and colleagues.[10] A combination of dexamethasone and plasmapheresis also did not reverse congenital complete heart block, although the fetal status appeared to improve.[128] Similar improvement was seen in other cases treated with corticosteroids.[129–131] The concentration of total maternal IgG and antibodies to SSA(Ro) and SSB(La) can be decreased by > 60% by this therapy.[132,133] The use of intravenous gammaglobulin has also been attempted.[134]

Maternal administration of ritodrine may increase the fetal ventricular rate and can be considered in life-threatening fetal bradycardia induced by complete heart block.[135] Such sympathomimetic drugs are effective but are poorly tolerated by the mothers.[136,137]

Pacing therapy

Ten patients ranging in age from 8 months to 15 years were treated with an implanted *P*-wave, synchronous epicardial pacemaker.[138] Furman also describes successful pacing in children,[139] and Vanetti and colleagues describe an early, large French series of 241 children with atrioventricular block 40.7% of which were congenital.[140] Early pacing systems demonstrated significant lead failures, short battery life (mean of 17 months) and possible complications of asynchronous pacing.[141] The development of epicardial steroid-eluting leads has improved the application of pacing systems.[142,143]

A single pass lead has been suggested to provide a simple means of reliable atrial synchronous ventricular pacing in growing children with complete heart block.[144–147] However, coexisting sinus node disease should first be ruled out.[148]

In 18 of the 24 children with disabling complete A-V block, pacemaker therapy provided relief of symptoms and prolonged life,[149] a finding confirmed by others.[150] Transvenous pacing can be accomplished in relatively young children.[151] The use of actively anchorable endocardial leads is recommended to allow for the placement of long electrode loops in the cavity of the right atrium without increasing the risk of dislodgement.[152]

Complications

Pacemaker therapy in sixteen children over a period of 56 patient years resulted in nineteen complications necessitating surgical treatment.[153] Lead complications may eventually occur in up to 50% of patients.[39] Pacing complications or failure were the cause of death in 2/16 patients with CCHB reported by Villain and colleagues.[154]

Medicolegal issues

CCHB is considered a contraindication to professional pilot status.[155]

Differential diagnosis

Anatomic heart disease was present in 25/65 (39%) infants with congenital heart block, with ventricular inversion/L-transposition of great arteries complex occurring most frequently (20/25 infants).[156] AV block in the face of structural heart disease may be present in the first trimester,[157] in contrast to patients with structurally normal hearts who usually present beyond 16 weeks of gestation.

In a series of 23 patients with congenital heart block, 7 cases were combined with a corrected transposition of the major vessels.[158] Fox described 26 patients with atrioventricular discordance and a variety of ventriculoarterial connections who have had appropriate intracardiac repairs. Seven of 26 patients (26.9%) died early postoperatively, but only 2 (11.1%) of 18 patients operated upon since May 1972 died. Ten patients (40%) developed permanent complete heart block.[159] In 40 patients with ventricular inversion and l-transposition of the great arteries reported by Gillette, there were 11 subjects with complete

AV block.[160] In the detailed series of Huhta and colleagues, atrioventricular block was present in 4/107 patients at birth. The risk of natural onset AV block continued at a rate of *c*. 2% per year after diagnosis. The presence of an intact ventricular septum made AV block more likely.[161]

Complete block below the His recording site was associated with syncope in one patient and sudden death in another.[160] Patients may have two AV nodes, connected by a Mönckeburg sling, but with neither node connecting to their respective bundles.[162] Corrected transposition with AV block may rarely complicate disorders of laterality such as Kartagener's syndrome.[163] Patients with corrected transposition may also have manifest accessory pathways. It should be recognized before ablation of such a pathway that this might be the only route of atrioventricular conduction.[164]

Inherited abnormalities characterized by conduction defects is association with atrial septal defects may occur without associated forearm defects.[165] Alternately, forearm defects may be associated through one or more inherited syndromes.[166,167]

Complete AV block is also frequently present in patients with left isomerism, a not unexpected finding since the AV node is a right atrial structure.[168,169] The incidence rate of complete A-V block in left isomerism is nearly 20% of the cases described.[170] The histological pattern of congenital complete heart block in cases with left isomerism is discontinuity between the AV node and the conduction axis, in contrast to the pattern of atrial-axis discontinuity produced in the structurally normal heart with CCHB related to maternal anti-Ro antibodies.[171]

Complete AV block may also occur in the presence of right atrial isomerism. The histology of the conduction system may demonstrate separate anterior and posterior AV nodes, neither connected with the atrial myocardium.[172]

Though diphtheritic infections are known to affect the cardiac conduction system, authenticated cases of post-diphtheritic block persisting after the infection are rare.[173] Fetal viral myocarditis has also been suggested as a cause for congenital heart block.[174]

Mesothelioma of the atrioventricular node may result in complete heart block, which may be present for many years before death.[175–178]

A syndrome of multiple lentigines associated with retardation of growth, hypertelorism, abnormal genitalia and complete atrioventricular block (LEOPARD syndrome) has been described.[163]

Long QT Syndrome

The long QT syndrome is a familial disorder of myocardial repolarization, which affects young people with structurally normal hearts. Defective genes that encode for ion channels expressed in the heart cause the repolarization abnormality that leads to torsade de pointes and, in some cases, to sudden death. The prolonged QT interval was considered for many years to be the hallmark of the disease, but it has been demonstrated that individuals with normal QT intervals may be gene carriers and may still be at risk of ventricular arrhythmias and sudden death.

Factors to consider in the diagnosis of LQTS include clinical symptoms, family history and prolongation of the QT interval on the surface ECG. Symptoms may include syncope, seizures or aborted sudden death, particularly in the setting of specific initiating events (see below). A family history of sudden death should be sought for. Keating[1] described criteria for considering a patient as affected, unaffected or uncertain, depending on the presence of symptoms and the QTc interval. Patients with symptoms and a QTc > 450 ms as well as those asymptomatic patients with a QTc > 470 ms were classified as affected. Asymptomatic patients with a QTc < 410 ms were classified as unaffected. The uncertain diagnosis group thus included both patients with symptoms and a QTc < 440 ms and patients without symptoms and QTc between 410 and 460 ms.

The Schwartz criteria (Table 49-1) are probably the most popular method for categorizing patients with suspected long QT syndrome.[2,3] The first proposed criteria were published in 1985 and included major and minor findings. Less than a decade later, prompted by new developments in knowledge about the disease, reassessment and diagnostic refining took place and the criteria were revised and republished in 1993. This update was based on observed gender-related differences in the length of the QT interval, the large spectrum of newly recognized clinical manifestations and the contribution of molecular biology to the understanding of LQTS.

Although these criteria, and indeed the majority of published data on LQTS, refer to older patients, a number of studies have specifically addressed the manifestations of LQTS in children. LQTS is a hereditary disease with different clinical characteristics and prognosis in children as compared to adults; children who present at younger ages most probably have the most severe form of the disease with a higher risk of sudden death. Children are more likely to present with sudden cardiac death as the first event than adults. Clinical studies performed in adults may be skewed in favour of those who survived.[4,5]

Incidence and prevalence

The incidence of LQTS in the general population is not known, but has been estimated by some authors to be *c*. 1 in 10 000–15 000 live births.[6,7] There are more data regarding the prevalence of LQTS amongst deaf individuals. Fraser identified 9 cases of Jervell–Lange–Nielson (JLN) syndrome amongst 1765 deaf children, and then extrapolated the prevalence of the JLN subtype of LQTS in children between 4 and 15 years of age living in England, Ireland and Wales as being between 1.6 and 6 per million.[8,9] In a meta-analysis of published series, Schwartz *et al*.[10] estimated the prevalence of LQTS amongst deaf individuals as 0.28%.

Two other studies have also reported on prevalence of LQTS in children with congenital hearing loss.[11,12] One of these studies investigated 350 school children between 6 and 19 years old with congenital deafness.[12] Eight children were identified as having a prolonged QTc above 440 ms. These children and their families were assessed for symptoms and QT prolongation on the ECG, 24 h ambulatory ECG, exercise test and echocardiographic results. The prevalence of LQTS among deaf-mute children in this study was 0.57%.[12] A case-control study from Turkey identified 5 patients with prolonged repolarization among 132 deaf children, with a prevalence of 3.78% in this population. The mean QT, QTc, JT and JTc intervals and the dispersion values were significantly longer than those of control subjects.[13,14]

Studies in the pediatric population (Table 49-2) have indicated that the proportion of JLN amongst identified LQTS populations is between 4.5%[4] and 9%[11] suggesting that the Romano-Ward variant of LQTS is at least ten times more common than JLN. However, difficulties in ascertaining the true incidence of LQTS in the non-deaf population give support to Schwartz's contention that LQTS is likely to be more "underrecognized than rare."

Data from the International Registry[15,16] demonstrated the proportion of the JLN variant in the general LQTS population to be between 6% and 10%. Subsequent data published in 1998[5] demonstrated the results of genetic testing in 38 large families. A total of 728 families were enrolled in the study at that point. There were 246 (45%) gene carriers among 541 genotyped family members. Currently, there is incomplete characterization of the entire genetic profile of the LQTS, which makes it difficult to establish incidence/prevalence figures, even when utilizing genetic information.

Table 49-1 Diagnostic criteria for the LQTS

Criteria	Points††
ECG findings*	
A QTc †	
≥ 480 ms^{-}	3
460–470 ms$^{1/2}$	2
450 ms$^{1/2}$ (in males)	1
B Torsade de pointes‡	2
C T-wave alternans	1
D Notched T wave in three leads	1
E Low heart rate for age§	0.5
Clinical history	
A. Syncope‡	
With stress	2
Without stress	1
B Congenital deafness	0.5
Family history¶	
A Family members with definite LQTS**	1
B Unexplained sudden cardiac death below age 30 among immediate family members	0.5

*In the absence of medications or disorders known to affect these electrocardiographic features.
†QTc calculated by Bazett's formula, where QTc = QT/$\sqrt{RR}$.
‡ Mutually exclusive.
§Resting heart rate below the second percentile for age.
¶The same family member cannot be counted in A and B.
**Definite LQTS is defined by a LQTS score ≥ 4.
††Scoring: ≤ 1 point, low probability of LQTS; 2 to 3 points, intermediate probability of LQTS; ≥4 points, high probability of LQTS. (Reprinted from Schwartz,[3] Copyright (1993), with permission from Lippincott Williams & Wilkins.)

Molecular diagnosis and genotype–phenotype correlations

Over the past decade, basic scientists in conjunction with clinical cardiologists have published an impressive amount of research on the long QT syndrome (Table 49-3).[17–26] Since the publication by Keating[1] in 1991, five loci associated with the Romano–Ward (RW) and Jervell-Lange-Nielsen (JLN) syndromes have been described to date. Specific locations on each chromosome have been determined and the genes encoding for ion channel proteins have been sequenced, with the exception of LQT4. There are still genes to be discovered, given that the genetic mutations described to date are responsible for only about 50% of the genotyped patients. [17]

Neyroud described three JLN children from two different families, in which LQT was inherited in an autosomal dominant pattern and deafness was inherited in an autosomal recessive pattern. Splawski described a similar scenario. These findings are suggestive that one form of JLN is caused by homozygous mutation in KVLQT1.[26,37] Heterozygous mutations in KVLQT1 cause RW syndrome (prolonged QT and no deafness), while homozygous mutations in KVLQT1 cause JLN (prolonged QT and deafness). Wang[7] suggests that in RW syndrome with heterozygous KVLQT1 mutation, there are still some functional potassium channels in the inner ear, and congenital deafness thus does not occur in these patients. In JLN patients with homozygous mutations in KVLQT1 there is no functional potassium channels formed in the heart and in the inner ear, the latter leading to deafness.

Genotype–phenotype correlation

The understanding of patients with LQTS has been refined since genetic characterization of each subtype allowed correlation with clinical aspects. Originally, two forms of LQTS were described based on the pattern of transmission, as autosomal dominant (Romano-Ward) and autosomal recessive (JLN).[9,10,27] There is a broad diversity in phenotypic expression of each LQTS subtype attributed to variable penetrance of genetic activity or variable function of the ion channels encoded by the responsible genes. Multiple publications[5,28–37] have described the phenotypic characteristics of each LQTS genotype, including differences between genotypes of baseline observations, triggers for cardiac events, and mortality (Table 49-4).

Evolution of diagnostic and management algorithms

- 1856–1937: isolated case reports.
- 1957: first complete description of the disease by Jervell and Lange-Nielsen – sudden death, ventricular arrhythmias and deafness.[39]
- 1963–1964: independent contribution from Romano and Ward, describing the same clinical features of JLN disease, but without deafness.
- 1966: Yanowitz demonstrated the effect of right stellectomy or left stellate ganglion stimulation on the ECG and QT prolongation.[40]
- 1971: two reports with opposite conclusions in the same year. Moss and McDonald: first left cervicothoracic sympathetic ganglionectomy with successful outcome.

Ratshin: demonstrated failure to shorten QT interval by left stellate ganglion blockade – question about the rationale for surgery, and left stellectomy was abandoned.

- 1975: Schwartz demonstrated T-wave alternans induced by left stellate ganglion stimulation.[41]
- 1975: Schwartz published the sympathetic imbalance hypothesis, suggesting left stellectomy and beta-blockade as therapies.
- 1976: Schwartz demonstrated that the protective effect of left stellectomy was in fact the increase in VF threshold, independent of the QT interval shortening.
- 1979: International Registry started.
- 1980: Schwartz suggested that the spectrum of LQTS might be larger that previously thought and that it may include patients with normal QT intervals.
- 1985: Schwartz suggested that there might be a possibility that the basic defect in LQTS could be an as yet unknown intracardiac abnormality that might decrease electrical stability with an attendant increase in myocardial vulnerability to the effect of sympathetic discharges.
- 1986: Moss and Schwartz proposed that the unknown intracardiac abnormality may be an alteration in one of the K^+ repolarizing currents.
- 1987: Eldar reports on beneficial effects of permanent pacing combined with beta blockers on the outcomes of the LQTS.[42,43]
- 1991: Keating identified linkage of the LQTS to Harvey ras-1 gene locus on the short arm of chromosome 11 in one large family.
- 1991: Towbin confirmed linkage to the Harvey ras-1 gene in 65% of 23 families, providing evidence for the genetic heterogeneity of LQTS.
- 1992: On longer follow-up, combined therapy proved to be less effective than previously thought.[44,45]
- 1995–1996: three LQTS genes were identified in 9 months' time.
- 1995: Schwartz provided evidence for gene specific differential responses to various interventions.
- 1997: Neyroud demonstrated that the JLN recessive syndrome is caused by homozygous or by compound heterozygous mutations.
- 1998: Priori provided first evidence that even the RW variant can be transmitted as a recessive trait.

Table 49-4 Clinical characteristics in common forms of LQTS

	LQT1	LQT2	LQT3

Table 49-5 Risk factors for mortality

Reference	Study type and year	No. of patients	Mortality at specific time points	Risk factors for mortality
Schwartz *et al.*[10]	Retrospective, 1975	203	5%/year	Deafness
Moss *et al.*[15]	Retrospective analysis of prospectively collected data, 1985	196	1.3%/year	Congenital deafness, syncope, female, previous TdP/VF
Moss *et al.*[16]	Prospective, 1991	3,343	0.9%/year	QTc, HR

Mortality

Left untreated, the long QT syndrome carries with it a significant risk of sudden death, particularly in selected patients with specific risk factors (see below). Multivariate analysis has demonstrated four variables as significant risk factors for cardiac events (syncope and sudden death): congenital deafness, history of syncope, female gender and prior occurrence of torsades de pointes and/or ventricular fibrillation (Table 49-5). The most potent risk factor was congenital deafness, present in only 6% of the population.[3]

The change in mortality rate from the reports of Schwartz[10] to Moss[15,46] from 5% per year to 1.3% per year may be explained as follows. In the first study, deafness (itself a predictor of the more severe JLN variant) was more prevalent, at 30% compared to 6% in the second study. Schwartz's patient population were less likely to be asymptomatic (3% vs. 43%), as well as less likely to be on beta blockers (25% vs. 96). These data suggest that there was a significant improvement in survival after adequate therapies were instituted for these patients.[3]

The 1991 report of the LQTS Registry[16] demonstrated important data with respect to mortality events. A total of 147 patients (4.4%) from the total population died before age 50. The mean age at death was 21 years. Mortality occurred predominantly in young patients (57% by age 20), in those with previous syncopal episodes, with marked QT prolongation and without antiadrenergic therapy. The cumulative probability of events using birth as time of origin has shown that by age 12, 50% of LQTS patients and 8% of the affected family members have had a cardiac event. Using date of enrollment as time of origin, the probability of events at 10 years of follow-up was 37% for probands and 5% for affected family members.[16]

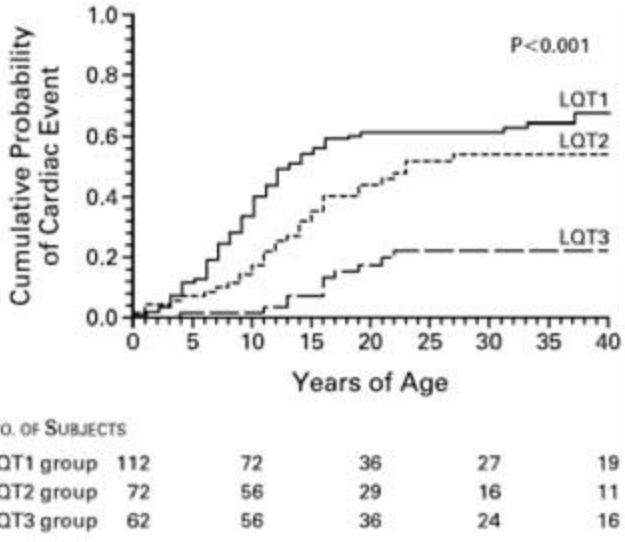

Fig. 49-1 Kaplan–Meier estimate of the cumulative probability of a cardiac event in genotyped LQT1, LQT2, and LQT3 patients. *P* value computed using log-rank test. Numbers of subjects at risk are given for each decade of age. (Reprinted from Zareba *et al.*,[5] Copyright (1993), with permission from Lippincott Williams & Wilkins.)

The third publication from the International Registry[5] evaluated the clinical course of LQTS based on genotype of the patients (see Fig. 49-1). Genetic testing was performed in 541 members of 38 large families with linkage analysis. The primary endpoints were syncope, aborted cardiac arrest requiring defibrillation and sudden cardiac death. Only events occurring from birth to age 40 were included to avoid possible confounding effects of ischemic heart disease or other diseases. Of the 541 genotyped, 246 patients were gene carriers: 114 had LQT1, 72 had LQT2 and 62 had LQT3 subtype. By age 15, there was a significantly higher proportion of LQT1/LQT2 patients (53% and 29%, respectively) who had had their first cardiac event when compared to LQT3 (6%). The frequency of cardiac events was significantly higher in LQT1/LQT2 patients (63% and 46% respectively) than among LQT3 patients (18%). However, LQT3 patients had a higher chance of death during a cardiac event (20%) than the other LTQS subtypes (4% each for LQT1 and LQT2).

Evidence-based strategies to improve outcomes

The international registry report published by Moss[15,46] in 1985 demonstrated that two interventions had significant beneficial effects reducing the occurrence of cardiac events during follow-up: left stellate ganglionectomy and beta-blocker therapy. This study was a retrospective analysis of prospectively accumulated data. While statistical techniques were used to adjust for risk differences between treated and non-treated patients to assess the independent effect of treatment on outcome, each physician individually decided the management of individual patients. As a result, the effects of therapy may have been over- or underestimated depending on selection bias of lower- or higher-risk patients, respectively. The recommendations were that patients with LQTS and high risk factors (congenital deafness, history of syncope, female gender and documented malignant arrhythmia) should be treated prophylactically with beta blockers in the maximal tolerated dose. Left stellate ganglionectomy was felt to

be indicated in patients with recurrent life-threatening arrhythmic episodes refractory to beta blockade. The recommendation for patients without risk factors but with positive family history of sudden death was to start beta blockers.

There is now general agreement that beta-blocker therapy is beneficial, and several studies have documented its efficacy in the prevention of syncope in 75–80% of LQTS patients.[3–5,15,16,46,47] However, beta blockers are not completely effective in preventing cardiac events, with a 20–25% risk of recurrent syncope and an ongoing risk of sudden cardiac death.[3] A study that included patients from the International Registry demonstrated that there is a significant reduction in the rate of cardiac events, although the patients who have the most benefit are those who were asymptomatic before starting therapy.[49] Another important issue to consider regarding effect of beta blockers in the majority of published retrospectively analyzed data is that therapy was usually used for those patients perceived to be at higher risk of cardiac events.

There is experimental evidence that the different subtypes of LQTS may have different responses to beta-adrenergic blockade. A study in canine myocardium where transmembrane action potentials were measured from epicardial cells, M cells and endocardial cells with a simultaneous recorded transmural electrocardiogram during infusion of beta-adrenergic agonists and antagonists demonstrated that beta blockers are protective in LQT1 and LQT2, but may actually facilitate TdP in LQT3.[50] These findings are in concordance with the observation that in the LQTS subtypes where the delayed rectifier potassium channels are defective and are usually dependent on an adrenergic trigger to the precipitation of ventricular tachycardia, beta blockers are effective. In sodium channel gene mutations, the role of beta blockers is not as well defined.[51]

Left cardiac sympathetic denervation

The sympathetic nervous system was initially thought to play a significant role in the pathogenesis of the LQTS. Surgical techniques to accomplish left cervicothoracic ganglionectomy improved the results in survival, but were not completely effective.[52]

The efficacy of LCSD in LQTS patients was demonstrated in a report on 85 individuals in whom a similar follow-up time was available before and after the procedure. The authors demonstrate a highly significant ($P < 0.0001$) decrease in the number of patients with cardiac events (from 99% to 45%), in the number of events per patient (22 ± 32 to 1 ± 3) and in the number of patients with five or more cardiac events from 71% to 10%. The authors conclude that the findings demonstrate that for LQTS patients who continue with syncope or cardiac arrest despite the use of beta blockers, LCSD is a very effective therapy.[52]

Bhandari described 10 patients with LQTS and recurrent syncope or cardiac arrest caused by ventricular arrhythmias that underwent left cardiac sympathetic denervation after failure of high-dose beta-blocker therapy. All patients had a prolonged QT interval at rest (548 ± 51 ms, mean ± SD) and corrected QT interval (QTc) (556 ± 43 ms). The QT interval shortened significantly after surgery, but the QTc interval still remained abnormally prolonged in 9 of 10 patients. On follow-up of 38 months, 8 of 10 patients had recurrent symptoms (cardiac arrest in 3; 1 death), syncope in 4 and presyncope in 6. Symptoms were not controlled with the addition of beta blockers, and resolved with more extensive sympathectomy (3 patients), pacemaker implantation (3 patients) and a cardioverter-defibrillator (1 patient). Only 1 patient remained asymptomatic without drug therapy or pacemaker-defibrillator.[53]

Cardiac pacing

While there are favorable data regarding the efficacy of cardiac pacing in preventing cardiac events in LQTS patients, pacemaker implantation in these patients is usually accompanied by beta-blocker therapy.[48] Thus the therapeutic effects of the two interventions are difficult to separate. A recently published study[54] with prospectively collected data and a retrospective analysis report data on isolated pacemaker therapy in a single family with 60 members affected by mutations in SCN5A (LQT3, Brugada). The authors considered the use of beta blockers a relative contraindication in this family with a strong history of sudden death at night in the presence of sinus bradycardia and bradycardia-dependent QT prolongation. Thirty affected individuals had a pacemaker implanted, with a prophylactic indication in 28 patients, while 2 of the 30 had symptoms (syncope). On follow-up of 4.5 years, none of the patients who had a pacemaker implanted had sudden death, while sudden death occurred in 5 patients among the remaining 30 without a pacemaker. This study, while small and non-randomized, demonstrates a benefit of isolated pacing therapy.

The rationale for the combined therapy approach with beta blockers and pacing was the prevention of pauses and the prevention of polymorphous ventricular tachycardia that might be triggered by increased adrenergic tone. Eldar *et al*.[42] suggested that the best mode of pacing for patients with the LQTS is DDD. The single atrial chamber pacing mode proved to be inadequate, with 5 patients having episodes of AV block. Two patients had syncope due to persistent episodes of 2:1 AV block.

Two pacemaker-programming strategies may be used to prevent post extrasystolic pauses and pause-dependent early afterdepolarizations and torsade de pointes. One method of preventing these pauses is to increase the pacing rate, but there are case reports of tachycardiomyopathy with the need for cardiac transplant on long-term pacing at higher rates.[55] Viskin proposed an alternative method for prevention of torsade de pointes by rate smoothing involving a pause-prevention pacing algorithm.[56]

Clearly there is a need for longer follow-up studies in these small populations with LQTS in order to assess more accurately the relative risk of malignant outcomes such as sudden death or aborted sudden death in patients with defibrillators. Dorostkar *et al*. showed a relatively high failure rate of combined pacing and beta-blocker therapy even in compliant patients (17%).[45]

Implantable cardioverter-defibrillators

In the largest cohort to date, with 37 patients treated with combined therapy with beta blockers and pacing, 28 (76%) compliant patients remained asymptomatic during a 6 year follow-up period. The rate of cardiac events (sudden death, aborted sudden death, appropriate ICD discharge and syncope) was 24% in all patients and 17% in compliant patients. Among the four deaths, there was one patient who died despite combined therapy and good compliance with beta blocker. Two adolescent patients died after discontinuing beta-blocker therapy, while on

combined therapy. The authors recommend "back-up" defibrillator therapy in high-risk noncompliant patients, in whom the risk of death and aborted sudden death was 57%.[45]

Resuscitated sudden death is an indication for ICD implantation in the LQTS patient, and the initial approach for such patients has switched from more conservative therapies in the past few years. The incidence of appropriate ICD discharges in higher risk populations of LQTS patients has been demonstrated to be 60%, at a follow-up of 31 months.[57]

Gene-specific therapy

The current therapeutic strategies for LQTS do not guarantee complete protection from cardiac events. Beta-adrenergic blockade, left cardiac sympathetic denervation, pacing and implantable cardioverter-defibrillators, isolated or in combination, have been shown to significantly decrease mortality when compared to no therapy, but better treatment options will hopefully be available in the near future. Molecular identification of various LQT genes and detailed description of their mutations should lead to the development of gene-specific therapy.[7] There is already important experimental and clinical evidence of the use of drugs and electrolyte infusions to manipulate ion channel activity and thus affect the abnormal repolarization characteristic of LQTS.[50,58–63]

Mexiletine, a Na^+ channel-blocking agent, shortened the QTc in patients with LQT3 related to abnormal Na^+ channels. It had only a modest effect on shortening of the QT interval in patients with other types of LQTS.[60] Elevated potassium concentration stimulates outward HERG potassium current.[64] Based on this finding, Compton *et al*. studied patients with LQT2 syndrome and demonstrated that increasing serum potassium concentration determined significant shortening of the QT interval from 629 to 425 ms.[59] Specific K^+ channel opening agents have also demonstrated promise.[61,62]

While gene-specific therapies for LQTS are effective in shortening the QT interval on the ECG, there are (as yet) no data concerning the clinical outcomes in terms of elimination of ventricular arrhythmias and the associated clinical manifestations of syncope, seizures and sudden death.[7]

Supraventricular Arrhythmias

Assessing the evidence

In identifying optimal practice in the management of pediatric arrhythmias, evidence from the literature should be assessed critically. However, many frameworks for the grading of evidence ignore all studies except large, randomized trials. This approach is impractical when assessing best practice for rare conditions such as pediatric rhythm disorders. However, the American Heart Association Committee on Emergency Cardiovascular Care have recently devised a set of evidence-based assessments (Table 50-1) which have been systematically applied to the formation of guidelines for cardiopulmonary resuscitation and emergency cardiac care.[1,2] The advantage of applying this system to recommendations in our limited population of children and young adults is that it allows for "evidence" from animal studies, mechanical studies, extrapolations of data, rational conjecture and historical acceptance of standard practice, with appropriate relative weighting.

Introduction

Supraventricular arrhythmias are defined as abnormal rhythms which require structures above the bifurcation of the bundle of His. They are classically subdivided into reentrant mechanisms, automatic mechanisms, triggered arrhythmias and other or undefined mechanisms. Reentry may be confined to normal structures, or utilize accessory conduction pathways.

Supraventricular arrhythmias in structurally normal hearts

Supraventricular tachycardias (SVT) of any mechanism may occur in grossly structurally normal hearts. Three mechanisms (accessory pathways tachycardias of Wolff, Parkinson and White (WPW) or concealed WPW, atrioventricular node reentrant tachycardia (AVNRT) and atrial ectopic tachycardia (AET)) make up the large majority of SVT in children, with the proportion of each mechanism changing during development (Fig. 50-1).[3] A relatively complete list of mechanisms, their presentations and electrocardiographic findings are presented in Table 50-2.

Reentrant tachycardias usually share a number of common features. They are usually paroxysmal in presentation, unless the tachycardia circuit is so long or the conduction velocity so slow that spontaneous termination (caused by an advancing depolarizing wavefront reaching a retreating line of refractoriness) becomes exceedingly unlikely. Reentrant tachycardias are often initiated by a single premature event, and may be similarly terminated by 1–2 premature events. Reentrant tachycardias should respond to appropriately delivered cardioversion by termination and a return to sinus rhythm, although such terminations can be exceedingly brief, or followed by immediate reinitiation.

Sinus node reentry

Sinus node reentry is a tachycardia of reentrant mechanism occurring in the high right atrium just beneath the superior vena cava with a normal P wave and activation of the high right atrium before the high left atrium.[4] An invasive study of the mechanism of supraventricular tachycardias in 103 children identified sinus node reentry in 10.[5] The sinus node consists of pacemaker cells surrounded by alternate cell types in either a gradient or mosaic model of tissue architecture.[6] These cells are able to drive the surrounding atrial tissue without being suppressed electrotonically, and reentry of excitation is typically prevented by entrance block. Injury to the sinus node area might be expected to result in an increased incidence of sinus node reentry, such as following the Mustard atrial baffle repair of transposition of the great vessels. Sinus node reentry has also been identified in a neonate, and could be terminated by adenosine.[7] Electrophysiological assessment demonstrated a prolonged sinus node recovery time.

Atrial muscle reentry

Atrial muscle reentry can be subdivided into macroreentry and microreentry, based on the ability of gross anatomical mapping techniques to identify a circuit. When a macroreentrant circuit occurs in adults, utilizes the IVC-tricuspid valve isthmus as a critical pathway, and is characterized by typical "P-wave" morphology and cycle length, it is termed atrial flutter. Atrial macroreentrant arrhythmias which occur following surgery for congenital heart disease are now termed intra-atrial reentrant tachycardia (IART) or incisional reentrant atrial tachycardia (IRAT), with the former term being the most accepted (see IART below). Atrial muscle reentry can be acutely converted with appropriately delivered cardioversion, and often with programmed or burst atrial pacing as well. Although most forms of macroreentrant AT are insensitive to adenosine, rarely macroreentrant AT with zones of decremental slow conduction can demonstrate adenosine sensitivity. Adenosine-sensitive AT is usually focal in origin and arises either from the region of the crista terminalis (inclusive of the sinus node).[8]

Table 50-1 Evidence-based assessments of supraventricular arrhythmias

Level 1	Statistically significant RCTs
1A	Meta-analysis of multiple positive RCTs, statistically significant results
1B	One of more positive RCTs, statistically significant results
1C	Meta-analysis with inconsistent but significant results
Level 2	Statistically insignificant RCTs
2A	Meta-analysis of positive RCTs, but not statistically significant
2B	One of more positive RCTs, not statistically significant
2C	Meta-analysis of inconsistent RCTs; not statistically significant
Level 3	Prospective, controlled but not randomized cohort studies
Level 4	Historic, nonrandomized cohort or case–control studies
Level 5	Human case series
Level 6	Animal or mechanical model studies
6A	Animal studies
6B	Mechanical model studies
Level 7	Reasonable extrapolations from existing data; quasi-experimental designs
Level 8	Rational conjecture (common sense); historical acceptance as standard practice

Congenital atrial flutter

The most common presentation of atrial muscle reentry in children with structurally normal hearts is "congenital atrial flutter." In a series of 3383 apparently healthy newborn infants studied in one region of England, one infant had atrial flutter.[9] In a series of 32 newborns or infants with tachycardia, six had atrial flutter.[10] This disorder has been recognized for many decades, and is usually not associated with any obvious cardiac malformation or maternal disease.[11,12] Possible exceptions include an association with maternal lithium use in case reports,[13] an association with persistent primary congenital hypothyroidism in 1/243 cases,[14] and an association with atrial septal aneurism.[15,16] However, a small case–control study did not demonstrate any difference in the incidence of atrial septal aneurisn between patients with or without atrial tachycardia.[17] In addition, an association with apparent concealed accessory pathways was reported in 3 of 9 fetuses/infants presenting with atrial flutter.[18] The atrial cycle length during flutter ranged from 135 to 180 ms (mean 149 ms; mean atrial rate 403 beats/min), and there is usually a 2:1 ventricular response to atrial flutter.[19] Although some infants may respond to medication such as digoxin therapy (7/21 in our experience),[20] conversion of the rhythm should be accomplished more quickly in severely ill infants, by cardioversion if necessary.[21] Heart failure or hydrops fetalis were present in 14/25 of our series.[20] Quinidine and verapamil should be avoided.[12,22] Adenosine is usually ineffective in achieving conversion,[23] but may be helpful for diagnosis.[24] Conversion can be achieved with atrial overdrive pacing,[10] which can now be successfully delivered through esophageal pacing[19] resulting in successful conversion in approximately 71% of cases.[25] Most studies now suggest that chronic therapy is unnecessary and that recurrences are rare.[19,20,26–28] Lisowski and colleagues demonstrated that of the 43 live-born infants diagnosed *in utero*, 12 were still in atrial flutter at birth. Electrical cardioversion was successful in eight of nine patients, and no recurrences occurred beyond the neonatal period. Four patients with fetal flutter and hydrops showed significant neurological pathology immediately after birth (Fig. 50-2).[29]

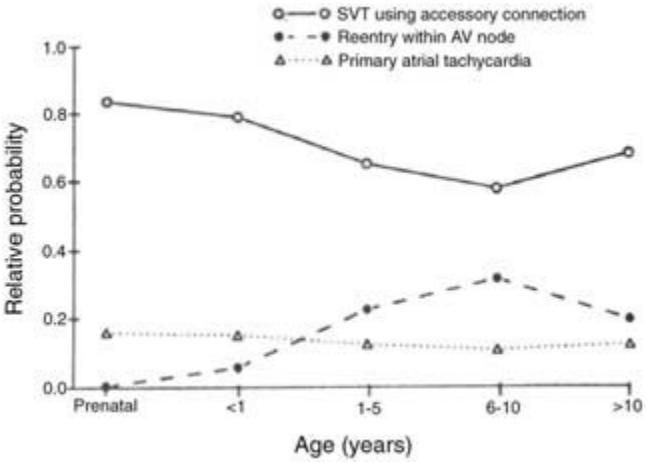

Fig. 50-1 (Reprinted from Ko *et al.*,[3] Copyright (1992), with permission from Excerpta Medica, Inc.)

Fetal atrial flutter

Fetal atrial flutter can be diagnosed by fetal electrocardiography[11] or fetal echocardiography.[30,31] Important advances in ultrasound technology, such as color coded M-mode Doppler[32] and tissue color Doppler ultrasound have greatly added to the accuracy of rhythm classification in fetal arrhythmias (Fig. 50-3). If cordocentesis is considered warranted, adenosine administration may be helpful in confirming the diagnosis.[33] One case report associates the presence of prenatal stenosis of the ductus arteriosus with fetal atrial flutter.[34] Another identifies idiopathic dilatation of the right atrium as an association.[35]

Jaeggi *et al.* published their own case series and a review of the literature in 1998,[37] the results of which are summarized in their table. Atrial flutter accounted for one-third of fetal tachycardias in their series, as in others.[38] The most consistent finding in their detailed review was the absence of recurrence of atrial flutter in follow-up, as confirmed by others (Fig. 50-4).[29]

Fetal atrial flutter is frequently associated with fetal heart failure (hydrops fetalis), death[39,40] or adverse neurological outcome,[29] although in one study the incidence of hydrops fetalis was no higher with atrial flutter than with other mechanisms of fetal tachycardia.[41] Fetal atrial flutter has been successfully treated by maternal administration of digoxin,[42,43] although this is less successful in achieving conversion than for other fetal supraventricular tachycardias.[40] Both digoxin and flecainide appear to have some success in the therapy of atrial flutter, with small case series suggesting combined efficacy in the face of hydrops fetalis,[44] and no adverse effects in most series.[45] Failure of digoxin may be related to differential digoxin levels attained between mother and fetus,[46] particularly in the face of placental effects of hydrops fetalis.[47] Sotalol has been effective at achieving conversion to sinus rhythm in eight of ten fetuses with atrial flutter.[48] As an alternative, intraperitoneal administration of antiarrhythmic drugs to the fetus in fetal tachyarrhythmias with severe hydrops fetalis has been achieved, with

Table 50-2 Supraventricular arrhythmias in structurally normal hearts: mechanisms, their presentations and electrocardiographic findings

Mechanism	Diagnosis	Presentation	Resting ECG	AV relation	PR or RP interval	P wave axis
Reentry	Sinus node reentry	Paroxysmal	Normal	1:1 or AV block	Normal PR	Normal
Reentry	Atrial muscle reentry	Paroxysmal	Normal	Variable or 2:1 AV block	Often 1° AVB if 2:1	Variable, Often – ve in 2,3,AVF
Reentry	AV node reentry	Paroxysmal	Normal	Usually 1:1	P under QRS	-ve in 2,3,AVF if visible
Reentry	His bundle reentry	Paroxysmal	Normal	1:1 or VA block	Short RP if 1:1	-ve in 2,3,AVF
Reentry with accessory pathway	WPW	Paroxysmal	Short PR and delta	1:1	Short RP (> 80 ms)	Variable
Reentry with accessory pathway	Concealed WPW	Paroxysmal		1:1	Short RP (> 80 ms)	Variable
Reentry with accessory pathway	Mahaim	Paroxysmal	Normal PR and delta	1:1	Short RP (> 80 ms)	-ve in 2,3,AVF
Reentry with accessory pathway	PJRT	Incessant	Normal	1:1	Long RP	-ve in 2,3,AVF
Automatic	AET	Incessant	Normal	1:1 or AV block	Often 1° AVB	Normal with P" in V2 or LAR
Automatic	JET	Incessant	Normal	1:1 or VA block	Short RP if 1:1	-ve in 2,3,AVF if 1:1
Triggered	NPJT	Incessant	Normal	VA block	VA dissociated	Normal
Other or unknown	CAT (MAT)	Incessant	Normal or 1°AVB	Variable AV block	N/A	Multiple (≥ 3) P morphologies
Other or unknown	AF	Incessant or paroxysmal	Normal	Variable AV block	N/A	No isoelectric baseline

PJRT, permanent form of junctional reciprocating tachycardia; AET, atrial ectopic tachycardia; JET, junctional ectopic tachycardia; NPJT, nonparoxysmal junctional tachycardia; CAT, chaotic atrial tachycardia; MAT, multifocal atrial tachycardia; AF, atrial fibrillation.

effective block of AV conduction.[49] In severe cases, drugs such as amiodarone can be administered by a combination of routes (intravenous, intraperitoneal and transplacental) to achieve conversion.[50] Protocols for the treatment of fetal tachycardias in general and fetal atrial flutter in particular continue to evolve.[51]

Atrioventricular node reentry

Paroxysmal reciprocating tachycardias of the AV node are characterized by prolongation of the P-R interval in the beat immediately preceding the tachycardia, and are generally accepted as being related to longitudinal dissociation of the A-V node.[52] The exact site of the reentrant circuit in AV nodal reentry remains controversial. While recent ablative techniques suggest that the atrium is required, other explanations for these interpretations are available. The AV node is a highly anisotropic structure and extends through Koch's Triangle. Data suggesting the atria are not necessary include the presence of AV dissociation during supraventricular tachycardia (SVT).[53]

Basic investigations in atrioventricular (AV) node reentry identify a dual AV conduction system, and atrial echo beats occurred when the refractory period of the slow conduction pathway is shorter than the fast pathway. Slow–fast AV node reentry (anterograde conduction over the slow pathway and retrograde conduction over the fast pathway) occurs most frequently. The fast–slow and intermediate varieties are much less common. AV nodal reentrant tachycardia can be cured surgically using direct AV nodal dissection (or perinodal cryoablation),[54] although surgery has largely been supplanted by catheter-delivered AV nodal modification. A high (> 95%) cure rate occurs with radiofrequency ablation with experienced electrophysiologists. Most electrophysiologists prefer the posterior approach, which results in absent or very poor conduction over the slow AV node pathway: the PR interval is minimally changed. This approach is highly successful for all three forms of AV node reentry and associated with a less than 1–2% incidence of heart block in most experienced laboratories.[55]

Atrioventricular node reentrant tachycardia is a moderately frequent cause on SVT in children, occurring in 8/33 children studied invasively by Gillette,[56] and in 25/103 children in a subsequent study.[5] However, dual A-V nodal pathways alone are common and may be a benign finding in arrhythmia-free children with heart disease.[57] Esophageal or intracardiac electrophysiologic studies can usually differentiate AV node reentry from other forms of SVT. The V-A interval was < 70 ms in 11/12 patients with AV node reentry versus more than 70 ms in all 16 patients with accessory pathway tachycardias.[58] Wolff and colleagues described atypical AV node reentry in two children in 1978. This unusual form of atrioventricular (A-V) nodal utilized a fast pathway for anterograde conduction and a slow pathway for retrograde conduction, the reverse of the usual form of A-V nodal reentrant tachycardia. In both cases the retrograde effective refractory period of the fast pathway was longer than that of the slow pathway, resulting in the establishment of this unusual reentry circuit. The patients had a superior P axis with a P-R interval shorter than the R-P interval during tachycardia.[59]

Multiple series of arrhythmia surgeries in children occurred in the era before radiofrequency catheter ablation, and most of these included children with AV node reentry tachycardia. The total efficacy of surgical treatment for all tachycardias was 97%[60] and 2/2 (100%).[61]

The pediatric RF ablation registry has been tracking procedures across multiple participating institutions for nearly a decade. Initial success rates for ablation of atrioventricular-node reentry (63 of 76 procedures) was 83%[62] In a single institution, Van Hare *et al*. demonstrated success in 15/17 children (88%).[63] By 1997, the pediatric RF ablation registry reported an immediate success rate of 96% for AVNRT, with a 71% freedom from recurrence at 3 years (Fig. 50-5).[64]

Bundle branch reentry

Based on our definition of SVT, bundle branch reentry may be defined as supraventricular if its circuit crosses the bifurcation of the bundle of His, or ventricular if it is entirely confined to one fascicle.[65] In either case, the features typically show a bundle branch block pattern of broad QRS, and a specialized conduction system potential preceding surface activation on intracardiac electrophysiologic study. Bundle branch reentries typically occur in several distinct patterns: They may be associated with dilated or ischemic cardiomyopathy. We have studied two such patients with dilated cardiomyopathy. One was treated with ablation of the bundle branch, but it recurred or the patient developed an alternate ventricular tachycardia several months later. The other was successfully treated with ventricular overdrive pacing through a permanent implantable defibrillator for

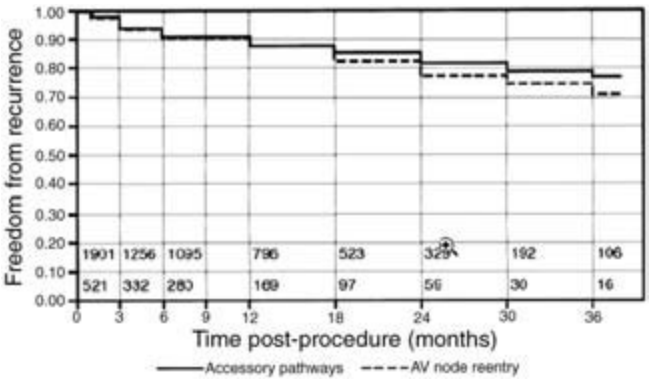

Fig. 50-5 Recurrence data for PSVT (Reprinted from Kugler *et al.*,[64] Copyright (1997), with permission from Excerpta Medica, Inc.)

many months before going on to receive a heart transplantation for worsening heart failure. In addition to bundle branch reentry in dilated cardiomyopathy which usually involves both bundle branches, tachycardia within the right bundle branch has only rarely been described.[65] Alternately, tachycardia may occur in a right bundle branch block, left axis deviation pattern (left posterior fascicular tachycardia) which is typically verapamil sensitive. This tachycardia has been described in multiple reports since 1981 and is often referred to as Belhassen's tachycardia.[66–69] This tachycardia may cause myocardial dysfunction in children if incessant, but usually responds to verapamil therapy.[70–73] In a small series of 8 patients, 5 patients eventually resolved their tachycardia spontaneously. Radiofrequency ablation was successful in 2 of the 3 patients with persisting tachycardia.[74] Ablation is usually successful, particularly when mapping is guided by the presence of a presystolic Purkinje potential.[75]

Wolff–Parkinson–White syndrome

In 1930, Wolff, Parkinson, and White described a series of young patients who had a bundle branch block pattern on electrocardiogram (ECG), a short PR interval, and paroxysms of tachycardia. Case reports began appearing in the literature in the late1930s and early 1940s, and the term Wolff–Parkinson–White (WPW) syndrome was coined in 1940. In 1943, the existence of an accessory connection between atria and ventricles was confirmed, which is about 50 years after Kent's description of myocardial fibers that were believed to conduct from atria to ventricle.

The term preexcitation was first published by Ohnell in 1944 (the same year that the term delta wave was coined); "preexcitation indicates an additional excitatory spread in the ventricles of the heart, coupled to auricular excitation." WPW syndrome is not the only form of preexcitation, but it is the most common. Initially, through the surgical treatment of WPW syndrome and, now, in the era of radiofrequency (RF) ablation, understanding of the pathophysiology of WPW syndrome has become refined in the wake of these elegant descriptions.

The first surgical division of an accessory pathway was performed at Duke University by Will C. Sealy, MD, in 1968. The first catheter ablation was reported in 1983, using DC energy; this was followed by the first successful RF ablation reported in 1987.

The underlying defect in WPW syndrome is the presence of an accessory pathway (AP) consisting of a myocardial connection at the atrioventricular (AV) junction. These are believed to be residual connections from the formation of the AV junction. The primary feature differentiating WPW syndrome from other AP-mediated supraventricular tachycardias (SVTs) is the ability of the AP to conduct antegradely (i.e. from atrium to ventricles) and retrogradely. The presence of this AP allows a reentrant tachycardia circuit to be established. In orthodromic SVT, the conduction is through the AV node to the ventricles, then back to the atria via the AP. Because the AP can conduct in both directions, it is also possible to experience antidromic tachycardia, in which the conduction from atrium to ventricle occurs via the AP, resulting in a broad complex tachycardia.

The presence of an antegrade AV connection also allows atrial arrhythmias to be conducted to the ventricles without passing through the AV node. Patients with WPW syndrome can more frequently develop atrial fibrillation, which can potentially be conducted to the ventricles rapidly (see Mortality/Morbidity). The different patterns of preexcitation have produced various classification systems. Classification by type is largely obsolete, and, currently, classification by anatomic location of the AP is used. The most common AP location is at the left free wall.

The incidence of the WPW pattern is unknown but is estimated to be 1–2 cases per 1000. This may be an underestimate, as it often represents an asymptomatic ECG finding. The incidence of newly diagnosed cases of WPW syndrome is approximately 4 per 100 000 population per year.

The incidence of sudden cardiac death (SCD) in WPW syndrome is approximately 1 in 100 symptomatic cases when followed for up to 15 years. Although relatively uncommon, SCD may be the initial presentation in as many as 4.5% of cases.

The cause of SCD in WPW syndrome is rapid conduction of atrial fibrillation (AF) to the ventricles via the AP, resulting in ventricular fibrillation (VF). AF develops in one fifth to one third of patients with WPW syndrome; the reasons for this and the effects of AP ablation on its development are unclear.

Certain factors increase the likelihood of VF, including rapidly conducting APs and multiple pathways. Cases also have been reported in association with esophageal studies, digoxin, and verapamil. A few reports document spontaneous VF in WPW syndrome, and SVT may degenerate into AF, thus leading to VF; however, both scenarios are rare in pediatric patients.

The morbidity in WPW syndrome results predominantly from AV reciprocating SVT. Even in the absence of VF, syncope is an occasional presenting complaint. However, in most patients, the SVT is well tolerated and not life threatening. If a patient experiences incessant tachycardia, cardiomyopathy may develop.

A male-to-female ratio of approximately 2:1 has been documented in some series. In other series, the syndrome was found to be more frequent in men (1.4 per 1000) than in women (0.9 per 1000). A recent Belgian study indicates a 3.5-fold higher prevalence of WPW in men than in women.

WPW syndrome may present at any age, with many cases presenting in infancy. A bimodal age distribution is observed in pediatric patients, with a second peak in school-aged children.

In several series, the incidence of associated congenital heart disease (CHD) is reported to be as high as 30%, most commonly Ebstein anomaly of the tricuspid valve and "corrected" transposition of the great arteries {S,L,L}. A genetic locus linking hypertrophic cardiomyopathy to WPW syndrome has been found on chromosome 7.

The findings of the underlying condition often become apparent only after the SVT has been terminated, although the hemodynamic consequences may be poorly tolerated in the presence of CHD.

APs are considered congenital phenomena, which are related to a failure of insulating tissue maturation within the AV ring. A proportion of patients with preexcitation may have a genetic predisposition. One example of such a predisposition is the association of preexcitation with a certain hypertrophic cardiomyopathy locus on chromosome 7.

Preexcitation can be created surgically, such as in certain types of Bjork modifications of the Fontan procedure, if atrial tissue is flapped on to and sutured to ventricular tissue. Certain tumors of the AV ring, such as rhabdomyomas, also may cause preexcitation.

Once identified and appropriately treated, WPW syndrome is associated with an excellent prognosis, including the potential for permanent cure through RF catheter ablation.

Concealed Wolff–Parkinson–White syndrome

Gillette studied 35 children with supraventricular tachycardia (SVT) and identified 8 with manifest or concealed "lateral anomalous pathway."[56] He describes these "concealed anomalous cardiac conduction pathways" as a frequent cause of supraventricular tachycardia. In a follow-up study of 103 children with SVT, a bypass tract was present in 51 and was concealed in 18.[5] These tachycardias are reentrant in nature and are included in the mechanisms underlying atrioventricular junctional tachycardias and atrioventricular reciprocating tachycardias. They are frequently initiated by a premature atrial or ventricular contraction,[76] and are a common cause of neonatal tachycardias.[77,78] Patients may have enhanced atrioventriicular conduction through the AV node facilitating tachycardia. In addition, a prolonged ventriculoatrial conduction time as demonstrated by a longer RP interval during tachycardia identifies infants whose SVT is more difficult to control.[79] The pathways may span the atrioventricular rings at any location, and can be abolished by surgical division along these areas.[80] The diagnosis can be verified by an esophageal atrial electrogram (AEGV) demonstrating a V-AEGM time of greater than 70 milliseconds, compared to V-AEGM times of less than 70 milliseconds in most cases of AV nodal reentry.[58] In addition to recording the AEGM, esophageal pacing can be used to initiate and terminate tachycardia.[81] A cycle length change of tachycardia when a bundle branch pattern occurs suggests that the pathway is ipsilateral to the bundle branch morphology.[82]

Several techniques have been used to ablate these pathways over the last two decades, including surgical division or cryoablation, DC shock catheter ablation,[83] radiofrequency catheter ablation[84,85] and catheter-delivered cryoablation.[86]

Permanent form of AV reciprocating tachycardia

In 1975, Coumel characterized the permanent form of junctional reciprocating tachycardia (PJRT), an entity which also bears his name (Coumel's tachycardia)[52,87] and is one of several mechanisms for incessant tachycardias in children.[88] Three years later, Gallagher demonstrated a number of features which characterize the mechanism of this tachycardia. The retrograde impulse was able to penetrate the atrium in two different areas, one near the region of the recorded His potential and the other near the orifice of the coronary sinus. Retrograde conduction persists after the creation of complete antegrade heart block (suggesting the existence of an accessory ventriculo-atrial connection). This provided supporting evidence that PJRT as an entity was likely different than atypical AV node reentry, which may present with a similar electrocardiogram. Para-Hisian pacing can also frequently separate PJRT from tachycardia mechanisms which do not rely on a septal accessory pathway.[89,90] The retrograde conduction has decremental properties suggesting that an accessory ventriculo-atrial nodal structure may be the underlying substrate of this arrhythmia.[91] Touboul described similar characteristics, as well as the surface ECG pattern of a relatively slow tachycardia, negative P waves in leads II, III and AVF, isobiphasic or negative P waves in the left precordial leads and a normal PR interval with long RP interval. The tachycardia started without lengthening of the PR interval or preceding extrasystoles.[92] An accessory pathway with a long conduction time is usually located in the posterior pyramidal space and provides the retrograde limb of the reentry circuit.[93] Such pathways conduct in a unidirectional retrograde fashion only, and have been demonstrated to be adenosine sensitive.[94] Other pathway locations along the AV groove and interatrial septum may occur,[95] as may multiple pathways.[96] P wave morphology may provide a clue as to PJRT pathway location.[97–99] Surgical ablation was a relatively successful therapy for patients presenting with PJRT in that era.[100] It could often be accomplished with a closed chest dissection, although occasionally an approach on cardiopulmonary bypass was required.[101] However, soon after this catheter ablation was applied,[102,103] and although early procedures were associated with complications of complete heart block or death,[102,104–107] the technique was eventually refined to utilize a radiofrequency energy source[108–111] and has become the standard therapy,[112,113] even in young children.[114,115] Medical therapy with amiodarone may be effective, and may allow for tachycardia-induced myocardial dysfunction to improve, but the tachycardia typically recurs with cessation of therapy.[116] Nevertheless, some authors recommend this conservative approach in infants and small children.[117,118]

The differential diagnosis of PJRT includes other accessory pathways with prolonged retrograde conduction times, but PJRT pathways should also show a decremental type of conduction and absence of antegrade conduction.[119,120] A subgroup of patients with slow or infrequent bursts of tachycardia can be identified and may not need treatment.[117]

Tachycardia-induced cardiomyopathy

The relatively slow tachycardia rates and normal PR interval of PJRT may occasionally be mistaken for sinus tachycardia if attention is not paid to the P wave morphology. In addition, prolonged incessant tachycardia may lead to a tachycardia-induced cardiomyopathy in these children. Occasional patients have been misdiagnosed as primary cardiomyopathy with sinus tachycardia and have been listed for transplantation.[121]

The majority of patients with PJRT and tachycardia-induced cardiomyopathy can be cured with radiofrequency ablation, following which their myocardial dysfunction usually resolves within approximately 6 months.[122–125] In one case, QT prolongation appeared to be a consequence of this tachycardia-induced cardiomyopathy, and an episode of torsades de pointes occurred following rate reduction by terminating the retrograde limb of tachycardia with RF ablation.[126]

Fetal PJRT

PJRT has been documented to occur *in utero*, where a long RP interval can be documented by measuring the ventriculo-atrial time interval on M-mode echocardiography.[127] Medical treatment *in utero* with amiodarone can be effective at reversing myocardial dysfunction.[128]

Mahaim tachycardias

The original descriptions of Mahaim were nodoventricular and fasciculoventricular fibers inserting within the right ventricle. It is now recognized that these fibers can also insert directly into the specialized conduction system of the right ventricle (right bundle branch). More importantly, it is now recognized that these structures most commonly arise from atrial tissue along the right atrioventricular ring. These pathways demonstrate decremental conduction, retrograde block and adenosine sensi-

tivity. It may be that "nodoventricular" fibers actually arise from the area of the slow pathway insertions to the AV node.

Mahaim fiber tachycardia typically involves antegrade conduction over this pathway with a resultant left bundle branch block and left axis deviation QRS morphology. The retrograde conduction is usually over the AV node, but occasionally over a second accessory pathway. In addition, Mahaim fibers may act as a bystander pathway to AV node reentry, not intrinsically being involved in the tachycardia but resulting in a broad-complex QRS morphology. A number of mapping strategies may be employed to localize and ablate Mahaim fibers participating in tachycardias. Atrial pace-mapping, introduction of late-coupled premature beats, "bump"-mapping and identification of accessory pathway potentials above or below the AV ring or deep in the right ventricular free wall have all been used with success.

Atrial ectopic tachycardia

Background: Atrial ectopic tachycardia (AET) is a rare arrhythmia; however, it is the most common form of incessant supraventricular tachycardia (SVT) in children. AET is believed to be secondary to increased automaticity of nonsinus atrial focus or foci. This arrhythmia, which also is known as ectopic atrial tachycardia or automatic atrial tachycardia, has a high association with tachycardia-induced cardiomyopathy. AET often is refractory to medical therapy and usually is not responsive to direct current (DC) cardioversion.

The diagnosis of AET is based on the presence of a narrow complex tachycardia (in the absence of aberrancy or preexisting bundle branch block) with visible P waves at an inappropriately rapid rate. The rates range from 120–300 and are typically higher than 200 bpm, although physiologic rates may be observed. The P wave axis is usually abnormal. Onset of the tachycardia occurs with a P wave identical to the subsequent P waves. The tachycardia may exhibit a "warming up," which refers to a progressively shortening P-P interval for the first few beats of the arrhythmia. Similarly, a "cool-down" period may be observed at its termination. First-degree atrioventricular (AV) block is typical and second-degree AV block is common. The tachycardia cycle length and degree of AV block are influenced by the autonomic tone.

Spontaneous depolarization is a phenomenon of automatic myocardium. The sinus node is usually the pacemaker of the heart because it has the most rapid spontaneous rate of firing. A small cluster of cells with abnormal automaticity is presumed to be responsible for AET. The conduction spreads from this cluster to the surrounding atrium and to the ventricles via the AV node. A conduction delay at the AV node often occurs, with most patients demonstrating first-degree AV block and some showing second-degree block.

Because AET often is incessant, tachycardia-induced cardiomyopathy is commonly observed. While the underlying mechanism of the development of cardiac dysfunction in the setting of chronic arrhythmias is unknown, numerous reports have documented improved cardiac function following ventricular rate control and treatment of the arrhythmia.

Although the exact incidence is unknown and few large series exist, AET is reported to comprise 5–10% of pediatric SVTs. Estimates of the incidence of pediatric SVTs vary greatly, but AET likely occurs with an incidence of approximately 1 in 10 000 children.

Tachycardia is generally well tolerated. Syncope is unusual, and cardiac arrest is rare, except when encountered as a complication of treatment. Tachycardia-induced cardiomyopathy is the most significant sequel of AET and may be insidious. The time it takes to develop is dependent on the rate and duration of the tachycardia, but dilatation may be present on initial presentation. This also can be reversed with successful treatment of the arrhythmia.

The arrhythmia is observed predominantly in infants and children; this accounts for a peak of 11–16% of tachycardias for which a mechanism is determined in young childhood. The adult form of AET may have a different etiology and natural history than the pediatric form.

AET is one of the incessant tachycardias, which may become associated with myocardial dysfunction if the average ventricular rate remains elevated over a long term.

Several reports have documented the spontaneous remission of AET in the pediatric population and in young adults. This may occur in as many as one third of patients following withdrawal of medication.[129]

Patients with AET should be monitored by a cardiologist. RF ablation can be curative and performed with a high degree of success, a low complication rate, and a low recurrence rate.

Junctional ectopic tachycardia

Background: Junctional ectopic tachycardia (JET) primarily occurs in two forms; idiopathic chronic junctional ectopic tachycardia is observed in the setting of a structurally normal heart, and transient postoperative junctional ectopic tachycardia occurs following repair of congenital heart disease. In addition, nonparoxysmal junctional tachycardia, which is a related but rare pattern of arrhythmia, can be observed in the setting of digoxin toxicity. JET is characterized by tachycardia for a person's age, which is being driven by a focus within or immediately adjacent to the atrioventricular (AV) junction of the cardiac conduction system (i.e. AV node–His bundle complex), but it does not have the features associated with reentrant tachycardia (e.g. AV node reentry). The tachycardia does not respond to a single extrastimulus and does not convert with programmed stimulation or cardioversion. The tachycardia may or may not have ventriculoatrial (VA) dissociation. Administration of adenosine results in VA dissociation without termination.

The pathophysiology of JET is unclear. Rare case reports have suggested that JET may be associated with progression to complete AV block. This does not appear to be the case in postoperative JET and has not been the author's experience in the rare cases of idiopathic JET. As implied by the synonym junctional automatic tachycardia, the mechanism may be automaticity. Others have suggested that triggered activity is responsible for this disorder.

The location of the responsible tissue probably is truly "ectopic" to the primary conduction pathway of the AV junction because JET has been treated successfully by the application of radiofrequency catheter lesions without the production of AV block. Junctional acceleration, albeit at a lesser rate than typical JET, is a recognized phenomenon during and following radiofrequency energy delivery for modification of slow pathway conduction in the therapy of AV node reentry.

Histamine, eosinophil cation protein, or other products of mast cell, eosinophil, or basophil degranulation that are liberated in response to cardiopulmonary bypass have been impli-

cated in the genesis of transient postoperative JET. The relative levels of various cytokines also may play a role. Low magnesium levels have been noted in children who develop JET following cardiopulmonary bypass surgery.

In one series, postoperative JET was identified in 7.5% of young patients undergoing Fontan procedures. In another series, postoperative JET requiring intervention was identified in 1.5% of infants undergoing the arterial switch procedure. JET is one of the most rare forms of supraventricular tachycardia in infants.

Postoperative JET usually occurs at an extremely vulnerable period following cardiac surgery, when nodal inflammation and/or ischemia may be present and ventricular function is often diminished. The additional insults of poor ventricular filling because of tachycardia and the loss of AV sequential contraction are considered to contribute significantly to morbidity and mortality. Congenital JET is an incessant tachycardia that usually results in tachycardia-induced cardiomyopathy.

Congenital JET is presumed to be present from birth but may not be identified until months or years later. Postoperative JET most commonly occurs in younger patients but also is known to occur in teenagers and adults following cardiopulmonary bypass surgery.

Congenital JET appears to be a chronic and unremitting condition. Curative attempts with radiofrequency catheter ablation therapy are probably warranted in patients with uncontrolled JET or if their size and age is sufficient to minimize procedural risks. Nevertheless, permanent AV block is a significant potential risk in the ablation of congenital JET.

Nonparoxysmal form of junctional tachycardia

The nonparoxysmal form of junctional reciprocating tachycardia is an extremely rare form of supraventricular tachycardia which may be seen clinically in significant digitalis toxicity. For this reason, it is suspected to be a triggered arrhythmia. Electrocardiographically it is characterized by a relatively slow, narrow-complex tachycardia with VA dissociation (Fig. 50-6).[130]

Chaotic atrial tachycardia

Chaotic atrial tachycardia has been defined as an irregularly irregular atrial tachycardia with three or more P wave mophologies and periods of isoelectric baseline (thus differentiating it from atrial fibrillation).[131] An adult disease, multifocal atrial tachycardia, has some similarities. Farooki and Green described multifocal atrial tachycardia in two neonates in 1977, and suggested that this was the first description of the entity in children,[132] although a number of prior reports existed.[133–137] The term "chaotic" is a general description of the irregular irregularity of both the atrial rhythm and its ventricular response, rather than a mathematical chaos in the rhythm, which has not so far been demonstrated.

Chaotic atrial tachycardia may occur in young children in isolation, in association with respiratory disease, or in association with specific entities such as Costello syndrome. One of the 9 patients described by Liberthson and Colan had bronchopulmonary dysplasia,[138] and in several patients with atrial tachycardias and respiratory syncytial virus infection, chaotic atrial tachycardia was documented.[139] Chaotic atrial tachycardia appears to be the typical arrhythmia of Costello syndrome.[140]

Atrial fibrillation

Atrial fibrillation has been a recognized arrhythmia in children for many years,[141,142] albeit rare in Europe and North America. Atrial fibrillation is more common in patients affected by rheumatic mitral valve disease, either primarily or following valve replacement.[143–145] Radford and Izukawa described a large series of 35 children identified in Toronto over 22 years.[146] The age of onset ranged from 1 day to 19 years (average, 8 years). Associated cardiac conditions were severe rheumatic mitral regurgitation (3 cases), cardiomyopathy (5), atrial tumors (2), infective endocarditis (1), paroxysmal atrial tachycardia of infants (4), idiopathic paroxysmal atrial fibrillation (1), Marfan's syndrome with mitral regurgitation (1), endocardial fibroelastosis (1), and structural congenital heart malformations (17). Surgical correction of congenital heart lesions was directly related to the development of atrial fibrillation in 14. The atrial fibrillation was paroxysmal or transient in 21 patients and persistent in 14. Digoxin was used in all cases and cardioversion attempted in ten. No patient was given anticoagulants in this series, and three children had cerebral emboli with residual defects. Within congenital heart disease patients, atrial fibrillation is frequently associated with severe systemic AV valve stenosis or insufficiency.[147]

The prolonged presence of an atrial septal defect is associated with the development of atrial flutter and atrial fibrillation. Patients who have delayed closure of atrial septal defects well into adulthood are more prone to these events.[148] Mitral valve insufficiency is a frequent associated finding. For those who have already developed atrial fibrillation or have a high risk of developing atrial fibrillation following surgery, performance of a Cox/Maze III procedure is a reasonable consideration at the time of repair.[149]

Atrial fibrillation can occur in children in the absence of obvious congenital or acquired structural heart disease.[150] Frequently, this has been reported as a familial occurrence in association with bradycardia and conduction disturbances.[151–154] Specific genetic defects predisposing to atrial septal defects and conduction system disease have been identified, as has a chromosomal locus for isolated familial atrial fibrillation.[155]

In the fetus and neonate, AF is almost always associated with an accessory AV connection. In this setting it is postulated that rapid AV reentry degenerates into AF; the natural history favors spontaneous resolution of tachycardia during the first year of

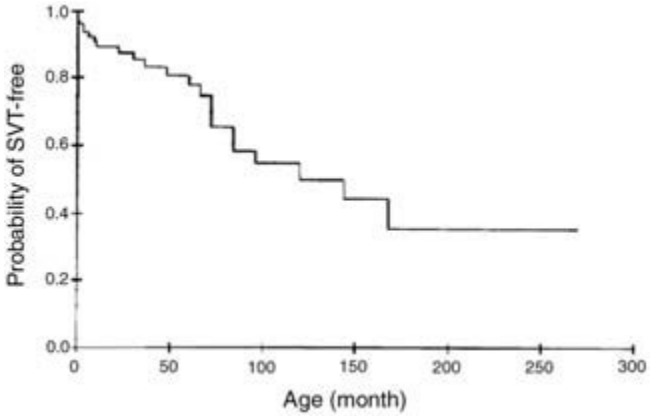

Fig. 50-7 Actuarial curve for the probability of being free from supraventricular tachycardia in 101 RAI patients. (Reprinted from Wu *et al.*,[159] Copyright (1998), with permission from The American College of Cardiology Foundation.)

life. A similar mechanism has been proposed for development of AF during paroxysmal supraventricular tachycardia in adolescents. Atrial fibrillation has been reported in association with dilated, restrictive and hypertrophic cardiomyopathies.

Supraventricular arrhythmias associated with structural heart disease

Atrial isomerism

Wren and colleagues reviewed electrocardiograms from 126 consecutive patients with atrial isomerism. Of 67 patients with left isomerism, 49 had sinus rhythm, 8 nodal rhythm and 10 atrioventricular (AV) block. Fifty-eight of 59 patients with right isomerism had sinus rhythm. Complete AV block was significantly more frequent in association with AV septal defect in left isomerism (5 of 45 patients) than in right isomerism (0 of 47 patients, $P = 0.049$). The P-wave axis was superior in 49% of patients with left isomerism. A significant shift of P-wave axis (> 90°) was seen on a subsequent electrocardiogram in 14 of 44 patients (32%) with left isomerism and 2 of 16 (13%) with right isomerism. Ambulatory electrocardiographic monitoring was performed in 17 patients. Based on these assessments, significant arrhythmias appeared to be rare, and did not appear to influence the natural history or affect the outcome of surgery.[156]

Momma and colleagues assessed the 15-lead electrocardiograms of 50 patients with left isomerism. In left isomerism, atrial rhythm with constantly normal P-wave axis was exceptional and the presence of atrial rhythm with abnormal P-wave axis was the rule. Slow atrial rates below the second percentile were observed in 50%, either transiently and recurrently (in 40%), or persistently (in 10%), and were associated with junctional escape in 42%. The number of patients with slow atrial rate increased with age. In right isomerism, multiple atrial rhythms were also frequent, but slow atrial rhythms was present in only 4%. Multiple atrial rhythms or bradycardia associated with junctional escape were rare in the group of patients with congenital heart disease and situs solitus. They concluded that multiplicity and progressive slowing of the atrial rhythm are characteristic in patients with left isomerism.[157] Wu documented Mahai-like pathways in two patients with left atrial isomerism.[158]

Wu and colleagues reviewed the prevalence and mechanism of supraventricular tachycardia in patients with right atrial isomerism. From 1987 to 1996, a total of 101 patients (61 male, 40 female) and four fetuses were identified with right atrial isomerism, with a median follow-up duration of 38 months. Supraventricular tachycardia was documented in 25 patients (24.8%) and one fetus (25%), with the age at onset ranging from prenatal to 14 years (median = 4 years). Actuarial analysis revealed that the probability of being free from tachycardia was 67% and 50% at 6 and 10 years of age, respectively. These tachycardias were converted by vagal maneuvers, verapamil, propranolol, digoxin, procainamide or rapid pacing. Seven cases had received electrophysiological studies, with reciprocating AV tachycardia induced in five and echo beats in one. The tachycardia in three patients was documented as incorporating a posterior AV node conducting in the antegrade direction, and an anterior or a lateral AV node conducting in the retrograde direction. Successful radiofrequency ablation was performed in two patients (Fig. 50-7).[159]

Cheung and colleagues also assessed that the conduction system in right atrial isomerism may be complicated by the presence of paired atrioventricular nodes. Symptomatic cardiac arrhythmia occurred in 15 of 85 patients (18%); 11 of the 15 patients had supraventricular tachycardia, and 1 patient each had atrial tachycardia, atrial flutter, ventricular tachycardia, and congenital complete heart block. The arrhythmias occurred before surgery in 4 patients, early after surgery in 5 patients, and late after surgery in 6 patients. Although 3 of the 7 patients who died suddenly had a history of symptomatic arrhythmia, arrhythmia was the documented cause of mortality in only 1 of the 32 fatalities (3.1%). Freedom from arrhythmia at 1, 5, 10, 15, and 20 years was 93% ± 3%, 86% ± 4%, 80% ± 6%, 73% ± 9%, and 48% ± 15% (mean ± SE), respectively (Fig. 50-8). No risk factors for symptomatic arrhythmia were identified by means of logistic regression. They concluded that although symptomatic cardiac arrhythmias are not uncommon, they do not seem to

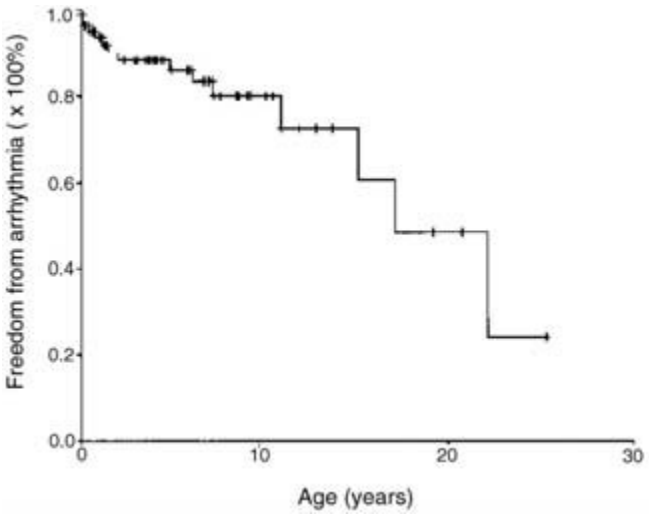

Fig. 50-8 Kaplan-Meier actuarial estimates of the probability of freedom from symptomatic cardiac arrhythmia in 85 patients who had undergone or were awaiting surgical interventions.

relate to the overall high mortality rate and occurrence of sudden death in this patient group.

Univentricular AV connections

IART in the Mustard/Senning patient

The Mustard and Senning atrial baffle repairs for correction of blood flow to repair transposition of the great vessels were devised several decades ago, yet we are still managing the electrophysiologic "fallout" of this operation. Late arrhythmias, particularly intra-atrial reentrant tachycardias previously termed "atrial flutter," have been recognized to be common for some time.[160,161] Over 50% of patients have inducible sustained atrial flutter at electrophysiologic study,[162] and at least a quarter of patients have clinical atrial flutter if assessed late postoperatively. Sudden death is frequent in this population, and associated with atrial flutter through recordings from case reports, as well as the similar bimodal pattern of risk that occurs for both atrial flutter and sudden death late after these repairs.[163,164] Impaired systemic right ventricular function is an additional risk factor for late death (Figs 50-9, 50-10).[164,165]

IART in the Fontan patient

Intra-atrial reentrant tachycardia, the name given to the complex atypical flutter often present in children following repair of congenital heart disease, is common following repairs utilizing the Fontan principle. However, IART can be reduced by modifying the type of Fontan operation, with fewer lateral tunnel Fontans having IART when compared to atriopulmonary connections.[166–168] The frequency of IART may be reduced even further by the use of a total extracardiac Fontan connection (Fig. 50-11).[169]

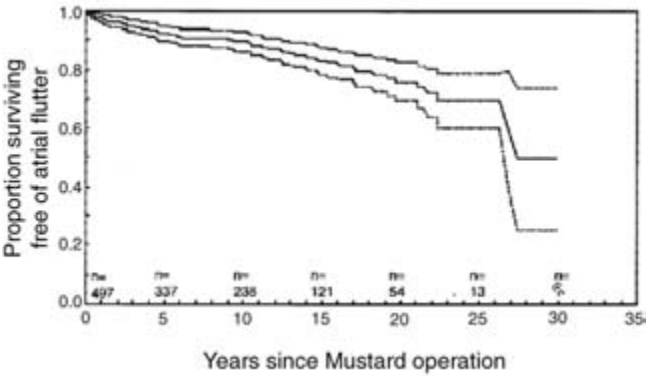

Fig. 50-10 (Reprinted from Gelatt, *et al.*[164], Copyright (1997), with permission from The American College of Cardiology Foundation and Excerpta Medica.)

IART in the other patients following congenital heart disease

TAPVD

Cardiac arrhythmias, particularly atrial flutter may occur late following repair of total anomalous pulmonary venous drainage in infancy, and are not predicted by age or adequacy of repair.[170] We have seen a high incidence of atrial flutter in our patients, as well as an occcasional patient with AV block.

Tetralogy of Fallot

Atrial arrhythmias, particularly atrial flutter, are common late following repair of tetralogy of Fallot, but usually occur beyond adolescence (Fig. 50-12).[170A]

Drug therapy

Most supraventricular arrhythmias will respond with a reduction but not abolition of symptomatic episodes. The appropriate medication depends on the underlying vulnerable substrate of the arrhythmia which can be targeted. This can often be identified from a 12-lead electrocardiogram in tachycardia. Atrioventricular node reentry responds well to digoxin, calcium-channel blockers or beta blockers, which slow conduction through the AV node. Accessory pathway mediated tachycardias are sensitive to Vaughan-Williams type 1 sodium channel blockers such as procainamide (1A) or flecainide or propafenone (1C), as well as type 3 potassium channel blockers such as sotalol or amiodarone.[171] Such pathway-specific medications may be particularly useful to reduce risk in patients with

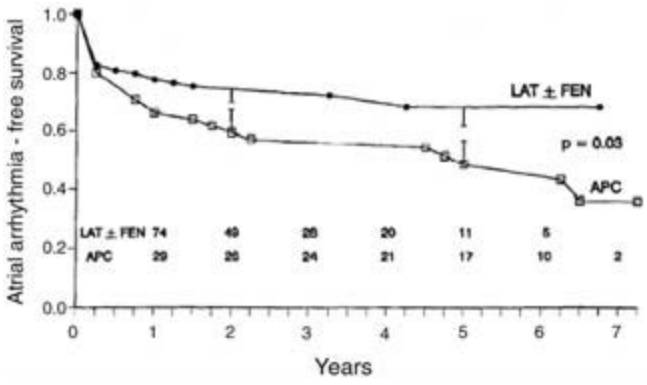

Fig. 50-11 Actuarial intermediate atrial arrhythmia-free survival after the Fontan procedure in patients with two different modifications: Lateral tunnel (LAT) with or without fenestration (FEN) versus atriopulmonary connection (APC). Fig. 50-13 Acute success rates for radiofrequency ablation of arrhythmias in children follow a negative exponential procedural learning curve which peaks at 95% in most centers.

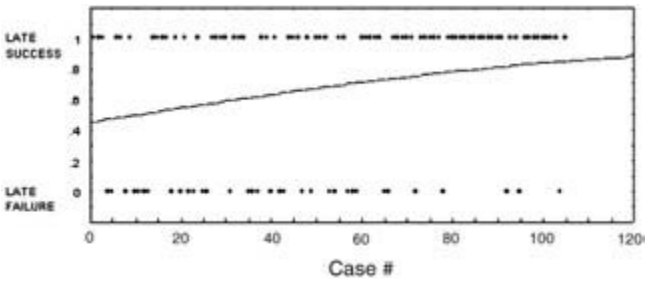

Fig. 50-14 Late (chronic) success following radiofrequency ablation of arrhythmias in children lags behind acute success in most centers.

Wolff–Parkinson–White syndrome with short antegrade refractory periods of the accessory pathway. On the other hand, digoxin and calcium channel blockers may accellerate the frequency of conduction over such pathways and increase the risk of frequent conduction of atrial fibrillation to the ventricle.

Automatic tachycardias appear to respond to procainamide with rate slowing, and may respond to propafenone, flecainide, sotalol or amiodarone with termination or reduction of the incessant tachycardia.

RFCA (Figs 50-13, 50-14)

Mapping methods

The majority of mechanisms of supraventricular tachycardia are amenable to curative catheter ablation. The potential success rate is likely related to the complexity of the anatomical substrate of the arrhythmia. If the vulnerable substrate of an arrhythmia can be localized to specific anatomical location, such as the slow pathway of AV node reentry or the accessory pathway of Wolff–Parkinson–White syndrome, ablation can often be accomplished using relatively simple imaging systems (biplane flouroscopy) and a limited number of recorded intracardiac channels. Anatomically, substrates such as the slow pathway of AV node reentry are limited to a limited number of locations on the surface of a complex three-dimensional structure (the posteroseptal space). When favorable anatomy guides the ablation catheter, such as in the substrate of a left-sided accessory pathway, one is essentially mapping sequentially along a curved line (the left AV groove). More complex anatomical substrates such as intra-atrial reentrant tachycardia (atrial flutter) may benefit from electroanatomical 3-D mapping systems to document areas of scar and critical isthmuses of conduction (Fig. 50-15).

Ablation methods

The mechanism for creation of an ablation lesion have evolved from relatively poorly controlled sources of energy (DC shock ablation) to finely controlled techniques (temperature-controlled radiofrequency catheter ablation) and now reversible mapping and ablation techniques (cryocatheter ablation). This new catheter ablation mechanism allows for a limited mapping and assessment of potential ablation outcome before creating a permanent lesion.

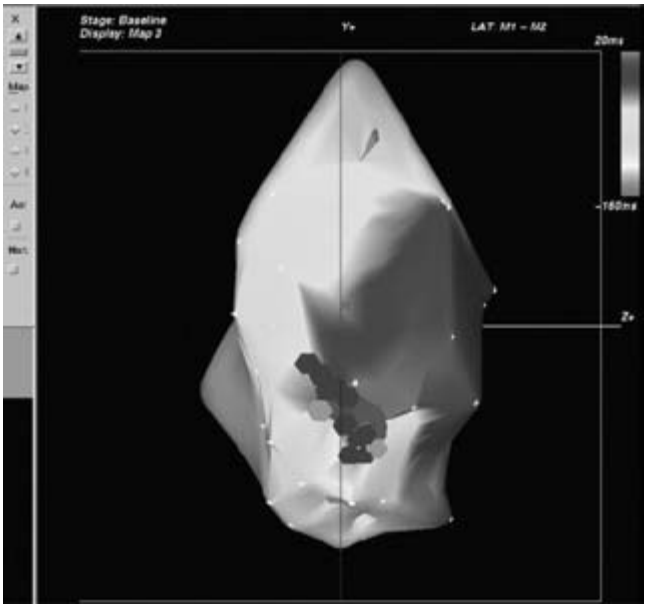

Fig. 50-15 Right lateral view of a right atriotomy flutter in a patient late following tetralogy of Fallot repair. The critical isthmus is identified above the area of breakout and between two marked points of double-potentials and was successfully ablated with a line of radiofrequency ablation lesions with no recurrence.

Outcomes

In a study of adults undergoing RF ablation, Cheng and colleagues demonstrated that radiofrequency ablation was the most effective and least expensive therapy for patients who have monthly episodes of supraventricular tachycardia.[172] Radiofrequency ablation improved quality-adjusted life expectancy by 3.10 quality-adjusted life-years and reduced lifetime medical expenditures by $27 900 compared with long-term drug therapy. Although the benefit of radiofrequency has not been studied in less symptomatic patients, a small improvement in quality of life is sufficient to give preference to radiofrequency ablation over drug therapy.

DeMaso and colleagues specifically studied children before and after radiofrequency ablation.[173] The patients showed reductions in the "fear of their heart problem" and increases in "the things that they enjoy," and those who had a successful ablation had better functioning than those who did not show improvement.

Pacing therapies

Pacing therapies can also be used successfully to treat atrial arrhythmias such as those following surgery for complex congenital heart disease. Rare complications or failures have decreased the enthusiasm for this technique.[174,175] Automatic overdrive pacemakers require excellent sensing of the atrial arrhythmia, an algorithm for identifying and discriminating the target arrhythmia and demonstration that repeated overdrive pacing is safe for the specific patient.

Even in the absence of an automatic atrial overdrive pacemaker, many of the current standard atrial or dual chamber pacemakers are capable of manual overdrive pacing, and may be very useful for patients with only occasional episodes of atrial tachycardia with mild or moderate symptoms.[176]

Patients at risk for atrial arrhythmias probably benefit from concomitant drug therapy to reduce the frequency of conducted impulses through the AV node at the time of their arrhythmia and delivery of pacing therapy. Digoxin appears to reduce the severity of symptomatology during episodes of atrial flutter, at least in patients following Mustard repair.[164] However, the use of antiarrhythmic drugs other than digoxin, and the frequency of hospital admissions can both be reduced.[177]

Ventricular Tachycardia

Ventricular ectopy comprises a broad spectrum of cardiac rhythm abnormalities ranging from isolated ventricular premature beats to ventricular fibrillation (VF), and including ventricular tachycardia (VT). The feature common to all of these is activation of most or all of the ventricular myocardium independently of activity in cardiac tissue that normally takes precedence in the intrinsic pacemaking hierarchy; namely, the sinoatrial node, atria, atrioventricular node, and proximal elements of the His-Purkinje system. Isolated ventricular premature beats are common in children,[1–4] as in adults,[5,6] and are usually benign when unassociated with identifiable structural or functional heart disease.[7–11] At the other end of the spectrum, VF occurring beyond the setting of controlled induction in the electrophysiology laboratory or with implantable cardioverter-defibrillator (ICD) testing is almost uniformly fatal in the absence of prompt and effective cardiopulmonary resuscitation and defibrillation, although rare cases of spontaneous recovery have been documented.[12,13] This chapter will deal primarily with VT, defined as at least three consecutive beats of ventricular origin occurring at a rate higher than that of the rhythm that immediately precedes or follows them. VT is a relatively uncommon tachydysrhythmia in children, especially in the absence of known predisposing factors enumerated below. Because VT is actually a manifestation of a heterogeneous collection of disorders with variable substrates and mechanisms, there are few pediatric outcome studies offering data from uniform patient groups large enough to provide a clear evidence-based approach to management. In many instances, therapeutic decisions are guided by extrapolation of data obtained in adults, by small published series of pediatric cases, or by anecdotal institutional or personal physician experience. The resulting nonuniformity in management further frustrates attempts at systematic outcome analysis.

VT is often described in mechanistic and/or morphologic terms. Like their atrial and atrioventricular counterparts, ventricular tachydysrhythmias can be mechanistically based upon enhanced focal automaticity or reentrant circuits. Additionally, triggered automaticity is recognized as a mechanism mediating ventricular tachydysrhythmias more often than is the case with supraventricular tachycardias[14,15] The electrocardiographic QRS axis and morphology of individual beats in VT, as well as their propensity to remain the same (monomorphic VT) or to vary (as in bidirectional or polymorphic VT), can provide important clues regarding the mechanism and anatomic focus of the arrhythmia. These, in turn, often suggest potential etiologies, prognoses, and treatment strategies, especially when cardiac or systemic conditions that predispose to VT are apparent. Indeed, such predisposing conditions are present in a substantial majority of pediatric patients with VT, and they serve as a logical conceptual framework within which to consider pediatric VT in greater detail.

Table 51-1 presents a classification scheme for pediatric VT based on predisposing or associated factors. Those acute systemic conditions whose remediation leads directly to permanent VT resolution, such as acidosis and electrolyte abnormalities, will not be discussed further. Also, VT occurring in the setting of surgically palliated structural congenital lesions,[16–28] in dilated cardiomyopathy,[29–36] in transplanted hearts,[37,38] and in the congenital Long QT syndromes (LQTS),[39,40] is discussed in chapters dealing specifically with those topics, and will not be addressed here. This chapter will focus mainly on "primary" or idiopathic forms of VT, and on recognized myopathic conditions in which ventricular tachydysrhythmias are a major manifestation.

Pediatric VT: historical overview

The general rarity of pediatric VT, and the pitfalls inherent in approaching it as a unitary condition, are underscored by a relative paucity of peer-reviewed literature on this topic.

In one of the earliest reports dealing specifically with pediatric VT, Palaganas and colleagues in Kingston, Ontario summarized the published experience from 1943 to 1965 as the background for their own presentation of a 6½-year-old VT patient.[41] Their search of the English language literature turned up only 17 previous cases, in which key pieces of clinical data were frequently unavailable. Of historical interest, 3 of 17 patients were said to have had diphtheria, and all 3 of these died. Only one patient was listed as having "no evident heart disease," and this one also had a fatal outcome.

The first effort to isolate idiopathic or primary VT in children was by Hernandez and coworkers, who in 1975 published a series of 7 patients aged 1 day to 13½ years with VT and no obvious predisposing factors.[42] Importantly, however, this study predated the widespread availability of reliable noninvasive imaging, and cardiac catheterization with angiography was undertaken in only 1 of their patients who in fact was known to have tuberous sclerosis. Four patients had syncope, hypotension, palpitations and/or dyspnea, while 3 were asymptomatic. Medical therapy varied. All had benign outcomes at follow-up of 6 months to 3 years.

In 1977, Radford *et al.* presented a series of 8 patients aged 6–16 years with VT or VF from the Hospital for Sick Children in Toronto.[43] This was the first report incorporating echocar-

Table 51-1 A classification scheme for ventricular tachycardia (VT) in children

Predisposing or associated condition	Example(s)
None (primary or idiopathic VT)	Accelerated idioventricular rhythm (AIVR)
	Right ventricular outflow tract (RVOT) tachycardia
	Idiopathic left ventricular (Belhassen's) tachycardia (ILVT)
	Bundle branch reentry tachycardia (BBRT)
	Catecholamine sensitive polymorphic VT (PMVT)
	Congenital Long QT syndrome (LQTS)
	Brugada syndrome
Myopathic processes	Arrhythmogenic right ventricular dysplasia (ARVD)
	Hypertrophic cardiomyopathy (HCM)
	Myocarditis
	Dilated cardiomyopathy
	Metabolic disorders
	Degenerative muscle disease
	Myotonic dystrophy
Infiltrative or invasive heart muscle diseases	Hamartomas
	Rhabdomyoma
	Fibroma
	Metastatic malignancy
	Sarcoidosis
	Chagas disease
Conduction abnormality	Heart block
Native structural congenital heart disease	Left ventricular or septal aneurysm
	Left ventricular outflow tract obstruction
	Coronary artery anomaly
	Mitral valve prolapse
Palliated structural congenital heart disease	Tetralogy of Fallot
	Aortic stenosis
Myocardial ischemia	Kawasaki disease
Metabolic derangement	Electrolyte disturbance
	Acidosis
Drugs	Antiarrhythmic agents
	Nonsedating antihistamines
	Cisapride
	Cocaine
Cardiac transplantation	Rejection or coronary insufficiency in donor heart
Trauma	Commotio cordis

diographic assessment of all the patients. Six had syncope and one complained of palpitations. Follow-up durations were not specified. This small but heterogeneous group represented a microcosm of conditions that subsequently have come to be more widely recognized as correlates of VT or VF in young people. It included 2 patients with sinus node dysfunction and chronic bradycardia, 1 of whom had left ventricular dysfunction; 1 child each with mitral valve prolapse, surgically palliated tricuspid atresia, long QT syndrome, and familial hypertrophic cardiomyopathy; and 2 with "idiopathic" ventricular ectopy. Of the latter 2, one was a 7-year-old boy with recurrent syncope, isolated ventricular premature beats suppressed during sleep, and angiographically impaired left ventricular contractility who experienced the only fatal outcome in the series, dying suddenly 6 months after diagnosis. The other was a 12-year-old boy, the only asymptomatic patient in the group, who had exercise-suppressed VT against a background of sinus bradycardia, and an apparently benign outcome with beta-blocker therapy that did not eliminate his ectopy.

Shortly thereafter, Pedersen and colleagues reported a similar but slightly larger series of 18 patients with VT or VF aged 4 days to 24 years at presentation (mean 16.6 years) who were followed for up to 70 months (mean 22.4 months).[44] This mixed group included patients with a variety of myopathic and metabolic problems, but with no recognized structural lesions other than mitral valve prolapse (4 patients) or "possible VSD" (1 patient) in any of the 16 patients who underwent imaging studies comprising at least M-mode echocardiography. Among 3 patients who died, 2 were young adults with dilated cardiomyopathy who experienced sudden death. The third was an 11-year-old girl with "progressive cardiac decompensation" who died nearly 3 years after presentation and had post-mortem evidence of an inflammatory process of undetermined etiology. Four of the 18 patients, including the only one known to be asymptomatic, had no identified cardiac or systemic issues apart from VT or VF. All of these had a benign course either with or without antiarrhythmic therapy (2 patients each); of note, 2 of these 4 patients had "VT" rates of 66 and 68 per min, suggest-

ing the inclusion of escape-like rhythm phenomena that would not be classified as VT in the current era.

Bergdahl and colleagues described primary VT in 5 boys presenting at ages ranging from birth to 11 years, with follow-up durations of 6 months to 11 years.[45] All had benign outcomes including VT resolution, and therapeutic success with quinidine was claimed for all 4 patients in whom it was tried.

While symptomatic patients predominate in most reported pediatric VT series, a group in Boston led by Fulton described 26 largely asymptomatic VT patients aged 1 day to 15 years at presentation.[46] Among this cohort, only 4 had symptoms at presentation and another 4 developed symptoms during follow-up as long as 34 years, averaging nearly 5 years. Nineteen of the patients had echocardiographic exclusion of significant structural and functional abnormalities, while in the rest this was accomplished by clinical assessment. It is noteworthy that none of the 26 patients died, and that all had apparently satisfactory outcomes notwithstanding a variety of therapeutic approaches. Moreover, there was no observable difference in outcome between 9 patients whose VT was induced or exacerbated by exercise, and 7 in whom exercise suppressed the VT.

As the approach to and understanding of arrhythmias became steadily more sophisticated, Deal *et al.* presented their 12-year experience with VT in 24 patients aged 1–21 years, with a mean age of 14.9 years.[47] Although prominently billed as a homogeneous group "without overt heart disease," 6 of the patients in this series had echocardiographic evidence of chamber enlargement or ventricular dysfunction, while 16 of 23 who underwent hemodynamic catheterization had functional abnormalities. Apart from 2 patients with mitral valve prolapse, however, all were free of identifiable structural heart disease. Among 8 asymptomatic patients, all were alive and well at mean follow-up of 7.3 years, including 5 who were not treated. Among the 16 symptomatic patients, including 2 who had presented with resuscitated cardiac arrest, there were subsequently 3 sudden deaths during a mean follow-up period of 7.6 years. The authors observed the following common features in the 3 patients who died: multiple spontaneous episodes of symptomatic VT, at least one cardioversion, abnormal findings at hemodynamic catheterization or post-mortem, and easily inducible VT with programmed intracardiac stimulation. None of these 3 patients was receiving antiarrhythmic therapy at time of death. Two of 9 patients with exercise-related VT were among the 3 who died.

By the time Noh *et al.* published their series of 18 VT patients aged 1 to 16 years,[48] an investigative approach incorporating echocardiography and intracardiac electrophysiology study with programmed electrical stimulation had become somewhat standardized. The main apparent purpose of this report was to describe the invasive study protocol utilized by the authors and its diagnostic yield in their group of patients. Unfortunately, the follow-up data provided were extremely limited, such that the observations elicited in the clinical cardiac laboratory could not be related to long-term patient outcome. Among 14 patients for whom follow-up data of unspecified duration were offered, there was no mortality.

A second report from our institution was published by Davis and coworkers in 1996.[49] Already the largest such series at the time with 40 pediatric-aged VT patients, this study also shifted the spotlight to a younger subpopulation by limiting inclusion to children – and, for the first time, 7 fetuses – aged 5 years or less at presentation, with a median age of just 0.2 years. Moreover, none of the patients had a recognized structural cardiac defect, although 1 had an aortic coarctation. Half of the patients had identified predisposing factors for VT including myopathic or inflammatory processes, tumors, and long QT syndrome, and such data were unavailable for the other 20 patients. Nine cases of VT were detected incidentally in "asymptomatic" patients, although the preverbal status of many of these children would have precluded subjective symptomatic complaints. There were 6 VT-related deaths, including 3 in infants < 1 week old and 2 sudden deaths in older children, as well as unrelated mortality in 3 other patients during follow-up ranging up to 14.1 years for all but 1 patient who was followed for 28.1 years. Only the presence of symptoms predicted a fatal outcome. VT resolved in a substantial majority of the children, with a median time to resolution of 0.3 years in 29 patients. All but 4 of those who ultimately experienced VT resolution were treated with at least one antiarrhythmic medication, but 24 of 29 were free of VT while on no medication at latest follow-up.

The largest, most recent and probably the most contemporarily relevant series of pediatric VT cases is that of Pfammatter and Paul, presented on behalf of the Working Group on Dysrhythmias and Electrophysiology of the Association for European Pediatric Cardiology.[50] This is the only multicenter study of pediatric VT to date, reporting retrospectively on 98 patients aged 0.1 to 15.1 (mean 5.4) years at presentation, with reasonably rigorous exclusion of all children with known factors predisposing to VT. Thus, it is arguably the only currently available study involving a substantial number of pediatric-aged patients with primary VT. Magnetic resonance imaging (MRI), increasingly considered to be an important diagnostic modality in VT patients, contributed to the exclusion of significant structural abnormality in 9 patients in this series. However, no biopsy data were presented. No cases of polymorphic VT were observed, possibly because catecholaminergic VT was specifically excluded. This could perhaps help to explain the remarkably benign courses and outcomes of the children in this study, as well as their relatively poor response to beta-blocker therapy. During 12–182 (mean 47) months of follow-up, there was no mortality, and all 98 patients had echocardiographically normal left ventricular function at last assessment. Moreover, 96 of the patients were asymptomatic at last follow-up, as compared with 36% who had symptoms either at presentation or at other times in the study period. VT resolved in 79 patients, including 63 who were on no antiarrhythmic medication. Seven of these had undergone successful transcatheter radiofrequency ablation of their VT focus, including 5 in the right ventricular outflow tract and 2 on the left ventricular aspect of the interventricular septum. Sixteen patients enjoyed complete VT control on chronic antiarrhythmic therapy, with amiodarone showing the greatest effectiveness (*c.* 80% total VT suppression plus *c.* 10% partial suppression) in comparison with verapamil, sotalol, propafenone, flecainide, and β-blockers, which were the least effective (*c.* 25% total suppression plus *c.* 10% partial suppression). Although not rigorously assessed, presumably because virtually all of the patients did well, the variable that appeared most highly predictive of a particularly good outcome such as early spontaneous VT resolution was presentation during infancy. Patients in the infant age group more often exhibited a left bundle branch block pattern electrocardiographic QRS morphology in VT, suggestive of a right ventricular focus, which itself was associated with a greater chance of VT resolution and lower incidence of symptoms even among the older patients.

Fig. 51-1 This 12 lead ECG recording was obtained from an 8-year-old girl 2 years after repair of a secundum type atrial septal defect. It shows accelerated idioventricular rhythm (AIVR) with left bundle branch block morphology and left axis deviation at 74 beats/min.

Primary or idiopathic VT

There is still some variability in the diagnostic classification of patients with VT occurring in the absence of identifiable systemic, structural or functional heart disease. However, incremental steps forward in our understanding of VT substrates and mechanisms have yielded a growing consensus in diagnostic categorization, accompanied by refinements in prognostication and management.

Patient records recovered through a computerized cardiology database search at the Hospital for Sick Children, Toronto, were reviewed and assigned to one of the following diagnostic categories wherever possible. Available data were inadequate for VT classification in 25 of the 73 records reviewed.

Accelerated idioventricular rhythm (AIVR)

AIVR is characterized by a regular monomorphic ventricular rhythm (Fig. 51-1) with rates that are just slightly more rapid than the prevailing sinus rate (Table 51-2). This apparently benign diagnostic entity is encountered in patients of all ages, but is decidedly rare in patients who fall outside the neonatal and infant age group.[51] In adults, AIVR is typically associated with postischemic reperfusion or with other types of myocardial pathology.[32] The distribution of AIVR in children follows the maturational transition from infancy, when associated heart disease is typically absent, to adulthood,[52] in other words, the older the child is at presentation with AIVR, the greater is the likelihood of discovery of myocardial disease. The association with myocardial disease has prognostic implications, in that the course of AIVR in such patients tends to track that of their underlying pathology. AIVR has a greater tendency to persist in patients with no apparent heart disease. AIVR is rarely dangerous in either group, however, and mortality is virtually unknown. Moreover, AIVR rarely responds to conventional antiarrhythmic therapy, such that the natural history is not significantly altered by treatment.

Among 12 identified patients with AIVR at our institution, mean age at presentation was 3.8 years. Symptoms were present in 16% of these children, but none experienced syncope, apparent life-threatening events, or cardiac mortality during an average 2.1 years of follow-up. Moreover, complete VT resolution was documented in all of them.

Right ventricular outflow tract (RVOT) tachycardia

RVOT tachycardia is one of the more common and benign types of idiopathic VT,[53] but diagnostic differentiation between RVOT tachycardia and the potentially more malignant myopathy known as arrhythmogenic right ventricular dysplasia (ARVD, discussed below) can be difficult, and is not always unequivocal.[54,55] RVOT tachycardia is most often characterized by paroxysmal runs of uniform nonsustained VT with an inferior QRS axis and left bundle branch block morphology (Fig. 51-2). It is often inducible with exercise and/or sensitive to adenosine. Lerman *et al.* have suggested that a mechanism based on cyclic AMP-mediated triggered activity could account for all of these characteristics.[56] Magnetic resonance imaging studies of RVOT tachycardia have revealed mild structural abnormalities in approximately 75% of patients,[57,58] but single-photon emission computed tomography (SPECT) using technetium-99m sestamibi/tetrofosmin might be more sensitive and specific in discriminating noninvasively between RVOT tachycardia and ARVD.[59] RVOT tachycardia usually maps electrically to the septal region of the RVOT, and transcatheter radiofrequency ablation of the VT focus has been applied safely and effectively in both adults[60] and patients in the pediatric age group.[61] VT ablation is usually undertaken to alleviate symptoms including palpitations, presyncope or syncope, as the natural history of untreated RVOT VT is almost invariably benign with respect to mortality or serious complications.[53] Moreover, RVOT VT is often sensitive to a wide variety of antiarrhythmic agents including simple beta blockers.[53]

Our database yielded records on 13 patients with RVOT VT, diagnosed at a mean of 3.5 years of age, and followed for 3.3 years on average. While symptoms were present in 63%, including 25% with syncope, there were no incidents of cardiac mortality, and all patients eventually experienced VT resolution including two who received no treatment. Among 10 patients for whom detailed documentation of medical therapy was available, 8 were successfully withdrawn from therapy and free of tachycardia at latest follow-up. Our RVOT VT ablation experience has thus far been limited to one success in three attempts.

Idiopathic left ventricular (Belhassen's) tachycardia

Another type of episodic VT occurring in otherwise normal hearts is commonly known as idiopathic left ventricular tachycardia (ILVT). This condition, whose ECG hallmark is a leftward QRS axis with right bundle branch pattern, was originally described by Zipes *et al.* in 1979[14] (Fig. 51-3). However,

Table 51-2 Diagnostic features of accelerated idioventricular rhythm (AIVR)

Diagnostic features
Monomorphic ventricular rhythm (usually LBBB morphology)
VT rate within 10–15% of prevailing sinus rate
VT runs begin with a fusion beat or with a "late" ventricular premature beat
Regular VT rhythm with mild acceleration or deceleration, especially before termination
Variable retrograde conduction resulting in suppression of the sinus mechanism

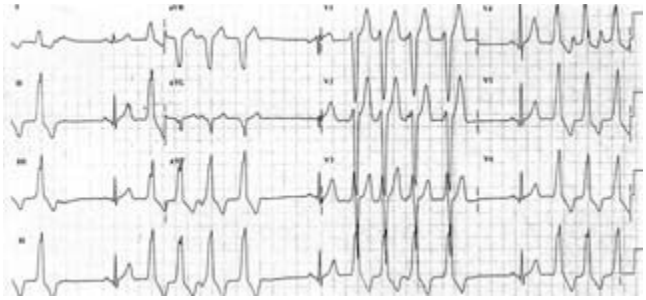

Fig. 51-2 Right ventricular outflow tract tachycardia (RVOT VT) in a minimally symptomatic 15-year-old male with a structurally normal heart. Typical features include short bursts of VT with inferior QRS axis and left bundle branch block morphology. He eventually underwent successful transcatheter radiofrequency ablation of an RVOT focus.

Belhassen's name is the one that became eponymously linked with ILVT after he and his colleagues characterized its striking susceptibility to suppression with verapamil.[62] In their original report, Zipes and coauthors presented evidence that the mechanism underlying ILVT is likely to be either reentry or triggered automaticity, most prominently including their observation that ILVT could be induced by atrial stimulation or sinus tachycardia.[14] Subsequent studies in isolated cases and small series of patients have supported either or both of these tachycardia mechanisms,[15;63–66] although more recent studies, cited below with respect to radiofrequency ablation, appear to favor reentry as the predominant mechanism.

The largest preablation era series involved 16 patients with a mean age of 33 years including 2 who were within the pediatric age range at 12 and 13 years old.[65] All 16 patients were symptomatic with palpitations at presentation, and 13 who received long-term oral verapamil therapy enjoyed significant or complete symptomatic relief during 1–6 (mean 2.8) years of follow-up. The same group subsequently reported long-term follow-up data from a larger group of 37 patients during a transitional period when transcatheter radiofrequency ablation was just becoming established as a therapeutic option.[67] Patients in this study had a mean age of 33 years at diagnosis and were followed for 1–13 (mean 5.8) years. They were classified by degree of initial symptomatic limitation into mild, moderate, and severe categories. None of the 14 patients with ILVT categorized as mild was treated, and none showed any significant deterioration during follow-up. ILVT was considered moderate in 17 patients, all of whom enjoyed a favorable symptomatic response to medical therapy which consisted of verapamil in the great majority of cases. All 6 patients with severe ILVT failed to respond to medication. Of these 6 patients, 4 subsequently underwent transcatheter radiofrequency ablation and one had cryosurgery. The only fatality among all 37 patients was the remaining patient with severe ILVT who died suddenly after implantation of an antitachycardia pacemaker.[67] Diltiazem appears to be as effective as verapamil in controlling ILVT.[68]

Because ILVT is usually symptomatic and there are reports of its culmination in tachycardia-mediated cardiomyopathy, transcatheter radiofrequency ablation has been readily embraced as a definitive cure,[69] with the first pediatric case report appearing in 1997.[70] The tachycardia focus or exit site usually maps to the left posterior fascicle,[71–73] although radiofrequency energy has been successfully applied at other sites on the septal surface of the left ventricle as well.[74–76]

Our institutional database search yielded 11 pediatric patients meeting diagnostic criteria for ILVT. They had a mean age at diagnosis of 4.4 years and were followed for an average of 1.8 years, during which there was no cardiac mortality, with apparent VT resolution in 90% of cases. Symptoms were present in 81% of this group, including syncopal events in 2 of the patients. Transcatheter radiofrequency ablation has been successful in five of six attempts.

Bundle branch reentry tachycardia (BBRT)

Bundle branch reentry is an unusual clinical entity most commonly associated with ventricular enlargement in the setting of dilated cardiomyopathy or other myocardial or valvular dysfunction.[77] BBRT is also associated with myotonic dystrophy.[78] It has only rarely been described in the absence of these functional or anatomic substrates,[79] with no published literature relating specifically to children. The right bundle branch forms the antegrade limb while the left bundle branch serves as the retrograde limb of a reentrant circuit which also incorporates the His bundle.[60] Electrocardiographic evidence of intraventricular conduction delay in sinus rhythm is the rule, and the QRS morphology in VT typically resembles that in sinus rhythm[60] (Fig. 51-4). Transcatheter radiofrequency ablation applied to the right bundle branch is usually successful in abolishing BBRT.[80]

Our cardiology database search yielded 4 patients with a diagnosis of BBRT in the absence of recognized functional or structural heart disease, presenting at a mean age of 4.7 years and followed for 2 years on average. Transcatheter radiofrequency ablation was attempted in 2 of these patients and was successful in 1. None of the 4 patients experienced cardiac mortality during the follow-up period, and BBRT apparently resolved spontaneously in 2 of them, with only the patient who underwent unsuccessful ablation continuing to experience episodic VT with palpitations.

Catecholamine sensitive polymorphic VT (PMVT)

Although relatively rare, catecholamine sensitive PMVT stands apart from other types of primary VT in three important aspects: it often has a malignant course and prognosis, it is

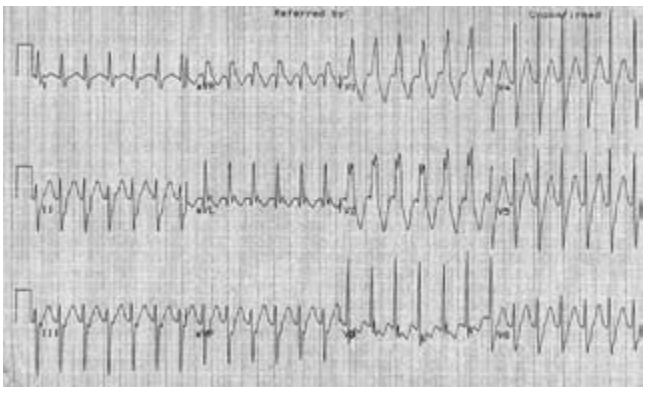

Fig. 51-3 Surface ECG recording showing ventricular tachycardia with RBBB morphology and left axis deviation characteristic of idiopathic left ventricular tachycardia (ILVT) at 191 beats/min in a 10-year-old boy with a structurally normal heart. There is evidence of VA dissociation most clearly shown in ECG leads I and II.

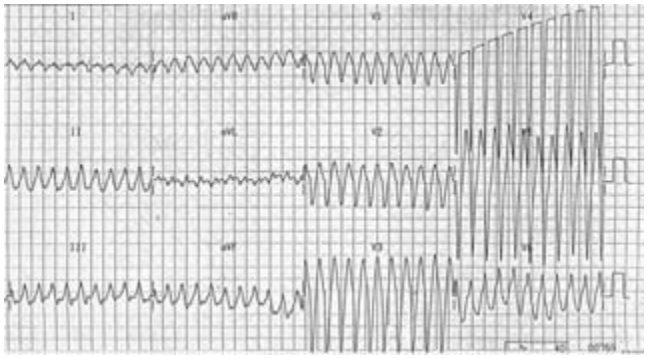

Fig. 51-4 ECG recording obtained from an 8-year-old boy with dilated cardiomyopathy and bundle branch reentry tachycardia (BBRT). There is a wide QRS complex tachycardia at 240 beats/min with left bundle branch block morphology, rightward QRS axis deviation and 1:1 VA relationship as evidenced by retrograde P waves in the inferior limb leads. Confirmation of tachycardia mechanism was obtained during electrophysiologic study which showed prolonged HV interval during ventricular tachycardia with this same morphology and VA dissociation. Subsequent ablation of the right bundle branch successfully abolished this patient's tachycardia circuit.

frequently familial, and its familial pattern of occurrence has in turn enabled the recent elucidation of its underlying cellular and molecular pathophysiology. PMVT features polymorphic or bidirectional (alternating QRS polarity) VT that is most often induced by exercise, emotional stress, or catecholaminergic stimulation of any source including isoproterenol infusion (Fig. 51-5). There had apparently been very few cases in the literature, including a series of 4 children reported by Coumel and coauthors,[81] when Leenhardt *et al.* published the first series establishing this condition as a unique diagnostic entity in 1994.[82] They described 14 young adult patients aged 35 ± 10 years who presented with syncope and were further characterized by a marked predisposition to ventricular fibrillation (10 patients) and sudden death (4 patients) during mean follow-up of 7 years. Their polymorphic ventricular ectopy was remarkable for strikingly short coupling to the preceding sinus beat, and for noninducibility with programmed stimulation.

As recently as 1997, Coumel puzzled over the cause of catecholamine sensitive PMVT and speculated about a possible etiologic relationship with the congenital LQTS.[83] Since 1999, however, when Swan and colleagues mapped autosomal dominant PMVT in two unrelated Finnish families to chromosome 1q42-q43,[84] major strides in molecular genetics have revealed that the key to this condition lies not in abnormal myocyte repolarization, as is the case in LQTS, but in intracellular calcium handling. Marks and colleagues[85] have summarized the rapid progress made subsequent to Swan *et al.*'s report,[84] culminating in the identification, to date, of 11 mutations clustered in three regions of the gene encoding the human cardiac ryanodine receptor known as RyR2.[86,87] This fruitful field of investigation is yielding exciting links not only between molecular abnormalities and their clinical cardiac phenotypic correlates, but also with diseases extrinsic to the cardiovascular system. RyR2 is the channel protein located in the sarcoplasmic reticular (SR) membrane that enables calcium-mediated calcium release, a key event in myocyte excitability and excitation–contraction coupling. Adrenergic stimulation results in RyR2 phosphorylation by protein kinase A, leading to increased release of calcium from SR stores. Abnormal calcium "leak" through RyR2 can induce delayed afterdepolarizations, which can in turn precipitate triggered tachydysrhythmias of the type seen in PMVT.[85] The 3 RyR2 regions thus far implicated in autosomal dominant PMVT are homologous to 3 regions in the skeletal muscle ryanodine receptor, RyR1, in which mutations associated with malignant hyperthermia (MH) and the degenerative neurologic disorder central core disease (CCD) have been identified.[85] Lahat and associates further consolidated the pathophysiologic connection between PMVT and impaired myocyte calcium handling. Having mapped a particularly lethal autosomal recessive form of PMVT found in Israeli Bedouin families to chromosome 1p13–21,[88] they went on to pinpoint a missense mutation in a highly conserved region of calsequestrin 2 (CASQ2), the protein that serves as the major SR calcium reservoir in cardiac myocytes.[89]

Leenhardt *et al.* reported on outcomes in 21 children with PMVT followed for an average of 7 years.[90] These patients had a mean age of 9.9 ± 4 years at presentation. All but 1 were symptomatic with exercise-induced syncope, and 30% had a family history of syncope or sudden death. Treatment with beta blockers resulted in complete symptom resolution, and a total of 3 syncopal events and 2 sudden deaths occurring in 3 treated patients during follow-up were attributed by the authors to probable or proven medication compliance issues. Fisher and colleagues described their 25 year experience involving 4 surviving affected members (father and 3 siblings) of a single family with PMVT and prior sudden death in 2 other siblings. Among the affected survivors, beta blocker therapy was effective in preventing untoward events during the extended follow-up period.[91]

With more recent advances in molecular diagnosis of PMVT, it should become possible to define outcomes in relation to specific mutations. Priori *et al.* investigated 4 families with autosomal dominant PMVT.[86] Among 11 individuals proven or presumed to be affected by RyR2 mutations, there were 2

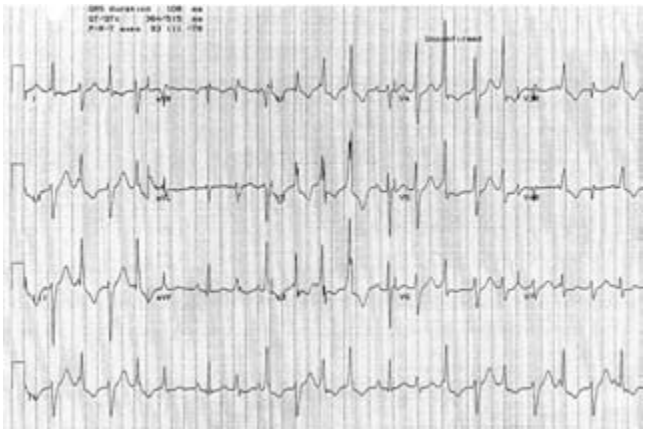

Fig. 51-5 Surface ECG recording from a 16-year-old girl with structurally normal heart who presented after a syncopal episode. She had nonsustained runs of bidirectional VT with a cycle length of 320 ms (note alternating QRS morphology in inferior leads). She responded well to beta-blocker therapy.

sudden deaths in typical circumstances, in sisters aged 14 and 16 years, and another in an unrelated 7-year-old boy whose identical twin presented with recurrent syncope. The authors provided 1–9 year follow-up data for 4 of 7 survivors, 3 of whom were treated with beta blockers, and 2 of whom underwent ICD implantation. All 3 medically treated patients enjoyed symptomatic relief from recurrent syncope. The 1 patient receiving both therapies continued to have short runs of VT documented by the ICD, but none apparently meeting criteria for device discharge. This was in contrast to the only ICD patient not treated with beta blockers, who experienced 2 ICD discharges in stressful settings during the first year of follow-up.[86] Bauce and colleagues recently demonstrated the feasibility and advocated the implementation of genetic screening in PMVT families with RyR2 mutations.[92] Patients from Lahat *et al.*'s Bedouin tribe, encompassing 7 related families with autosomal recessive PMVT, exhibit symptoms that are particularly severe and early in onset. Among 22 patients with proven or presumed PMVT, there were 9 sudden deaths occurring at age 7 ± 4 years, and 12 of 13 survivors have experienced recurrent syncope and/or seizures beginning at age 6 ± 3 years. Most of the survivors have responded favorably to beta-blocker therapy.[88]

Four of the patients in the Hospital for Sick Children cardiology database met our diagnostic criteria for PMVT. They presented at an average age of 9.5 years and were followed for a mean of 4.1 years, during which 1 patient (25%) experienced cardiac death. Two others had syncope or acute life-threatening events, and all 4 suffered from VT-related symptoms.

Brugada syndrome

The Brugada syndrome, first described in 1992 by 2 of the 3 brothers whose name it bears[93] and subsequently characterized more fully by all 3 of them in 1998,[94] is a novel ion channelopathy whose electrocardiographic hallmark is right bundle branch block QRS morphology and right precordial ST segment elevation in sinus rhythm. Sodium channel blocking agents such as flecainide and ajmaline are utilized diagnostically to accentuate the ECG abnormality in borderline cases,[95] and can also be arrhythmogenic in these patients.[96] Brugada syndrome is now known to be due to at least 3 autosomal dominant mutations in the cardiac myocyte sodium channel SCN5A with variable phenotypic manifestations involving loss of channel function and altered kinetics of recovery from inactivation.[97,98] These predispose the heart to sudden episodes of ventricular fibrillation, with predictably high mortality. The disease is typically one of adult males of Southeast Asian origin, although increased physician awareness has led to its recognition in other populations as well[95] None the less, the number of well-documented pediatric cases remains extremely small.[96,99,100] This is probably owing to age-dependent penetrance, with phenotypic expression in males, who account for 80–90% of affected individuals, peaking in the third and fourth decades of life.[101] The clinical heterogeneity of Brugada syndrome is increasingly well recognized,[102,103] and risk stratification strategies based on relatively substantial patient numbers are just beginning to emerge.[95,102] However, the applicability of recommendations arising from these reports to the pediatric population cannot be evaluated at this time. The issue of risk stratification is nontrivial, because no effective pharmacologic therapy has been identified to date, and ICD implantation represents the only life prolonging intervention presently available.[95,101]

VT associated with cardiomyopathies

Arrhythmogenic right ventricular dysplasia (ARVD)

ARVD is an uncommon condition which has nevertheless inspired a great deal of interest and numerous publications in recent years for the following reasons: (1) it is an increasingly recognized cause of arrhythmic mortality in otherwise healthy young people, accounting for one-quarter of cases of cardiac arrest or sudden death in athletes according to one Italian study;[104] (2) it can be difficult to differentiate from RVOT VT, a more common and usually benign condition; (3) its cellular and molecular underpinnings are the subject of a fruitful field of ongoing investigation. From the perspective of this chapter, ARVD is of added interest because it is the prototypical structural cardiomyopathy in which VT serves as the cardinal clinical manifestation.

Although earlier publications probably hinted at ARVD as a distinct clinical entity, the most widely cited benchmark case series is that of Marcus in collaboration with Fontaine and others, published in 1982.[105] These two authors have continued to write prolifically on the topic, generating, among other important contributions, a series of review articles chronicling many of the key steps leading to our current understanding of ARVD.[106–114] The interested reader is referred to these helpful resources, as all but a superficial survey of the copious ARVD literature is beyond the scope of this chapter.

Transmural fibrofatty replacement of RV myocardium is the pathologic *sine qua non* of ARVD,[105] and its demonstration at surgery or necropsy was defined as the diagnostic gold standard for ARVD in the criteria proposed by McKenna *et al.* in 1994.[115] However, fatty infiltration of RV myocardium can apparently occur in the absence of ARVD.[116] While ARVD was initially considered to be a disease specifically affecting the right ventricle, there are now numerous published examples of biventricular involvement.[117–123] The cause of progressive fibrofatty replacement of the myocardium in ARVD remains unknown. Recent identification of several seemingly unrelated pathogenetic factors including RV myocyte apoptosis,[124,125] mutations in novel genes of uncertain function,[126–133] and the presence of cardiotropic viruses in affected tissue[134,135] suggest that the pathologic features of ARVD might represent a final common pathway for a diverse group of etiologic agents, or the result of synergistic interaction among them. Familial cases, accounting for an unclear percentage of all ARVD patients, have been mapped to at least six different autosomal dominantly transmitted chromosomal loci, yielding a classification system (ARVD1–6)[136] that has yet to find general clinical acceptance or application. Among these subtypes, ARVD2 has the most clearly defined gene product, which interestingly happens to be the RyR2 ryanodine receptor implicated in PMVT (see above).[85,92,136] This link might provide an early clue regarding the propensity of ARVD to manifest clinically with ventricular arrhythmias, which otherwise remains unexplained.

The clinician faced with a suspected case of ARVD must often deal sequentially with two conundrums: first, differentiation of ARVD from RVOT VT, which features electrocardiographically indistinguishable VT and is considered to be far more common and more benign than ARVD; and second, an attempt at risk stratification based on fragmentary clinical outcome data in this heterogeneous disorder or group of disorders. In addition to relatively routine cardiac investigations

including standard electrocardiography, echocardiography[137,138] and cardiac catheterization with right ventriculography,[111] a number of more esoteric tests have been promoted as useful tools in establishing the diagnosis of ARVD. These include signal averaged ECG,[139–142] detection of so-called epsilon waves[111] and/or quantification of QT[143] or QRS[144] dispersion on standard 12-lead ECG recordings, Fourier phase analysis of gated blood pool single-photon emission computed tomography (GBP SPECT),[145] SPECT using technetium-99m sestamibi/tetrofosmin,[59] and even the measurement of plasma brain natriuretic peptide (BNP) levels, which have been shown to be elevated in patients with ARVD but not in those with RVOT VT.[146] Endomyocardial biopsy is not free of risk, and its diagnostic sensitivity can be confounded by the patchy nature of fatty RV myocardial infiltration and its typical distribution in the RV free wall rather than along the septal surface where tissue can be sampled most safely. A positive biopsy is none the less considered to be diagnostic of ARVD in the presence of other supportive findings.[115,147] In recent years, there has been great interest in the use of MRI which, in addition to being noninvasive and hence safer than cardiac biopsy, is quite sensitive and specific for detection of fibrofatty replacement of myocardium with fat.[148–151] Unfortunately, the sensitivity of this imaging modality also reveals myocardial fat deposition in a significant proportion of patients with presumed RVOT VT,[58,152] thus bringing into question its utility in differentiation between the two conditions, not to mention an as yet undefined degree of clinical overlap between them.

Outcome studies in ARVD are limited in number and the older ones are cited in reviews mentioned above. They are confounded by heterogeneity of the disease itself, of the diagnostic criteria employed in gathering data, and of the therapeutic interventions that have been utilized in its treatment.[153–158] No outcome information pertaining specifically to children is currently available. Berder and coauthors presented retrospective outcome data on a cohort of 49 men and 23 women presenting with ARVD at age 40 ± 13 years and followed for a mean of 4.5 (range 1–14.3) years.[159] According to the authors, 57 of their patients (79%) met the ARVD diagnostic criteria that were then just newly proposed by McKenna *et al*.[115] Three patients died, with 2 of the deaths attributed to complications of therapy. All but 11 of the surviving patients received treatment with a variety of antiarrhythmic medications given alone or in combination, direct current or radiofrequency ablation, and surgery comprising ICD implantation, right ventriculotomy or right ventricular disarticulation (also used in one of the patients who died). Meaningful conclusions are difficult to extract from these data, but it is noteworthy that most of the surviving patients were asymptomatic at latest follow-up, including 8 of those without treatment. In another retrospective analysis involving 121 ARVD patients of sex and age distribution similar to that of Berder *et al.*'s study, Peters and colleagues identified male sex, a variety of ECG measures of abnormal QRS dispersion and ventricular repolarization, RV enlargement, and left ventricular regional wall motion abnormalities as predictors of arrhythmic events severe enough to precipitate near or actual sudden death.[160] However, they did not describe actual patient outcomes or specify follow-up durations. Niroomand and coworkers recently compared electrophysiologic findings and outcomes in 15 patients presenting with ARVD meeting the McKenna criteria at 37.4 ± 16.4 years of age, and 41 patients assigned a default diagnosis of RVOT VT by exclusion of ARVD at age 40.1 ± 13.4 years.[161] In general, the ARVD patients were found to have more severe symptoms including syncope in 33% vs. 5% in the RVOT VT group, and cardiac arrest in 14% as compared with none among the RVOT VT patients. There were no deaths in either group, but VT and associated symptoms tended to be more resistant to therapy in the ARVD group than in the RVOT VT group. While this study is of some interest in the absence of more definitive data, its value is diminished by small patient numbers, by variable therapy and intervention, and especially by a very brief follow-up interval described by the authors as "around two years in both groups."

Hypertrophic cardiomyopathy (HCM)

VT is a well recognized and sometimes lethal complication of HCM. Citing an annual sudden death incidence of 1–4% in HCM patients, Elliott and coauthors assessed mid-term survival in 16 HCM patients aged 19 ± 8 years with documented sustained VT with syncope or resuscitated VF.[162] Excluding 1 patient who succumbed to neurologic complications of his initial cardiac arrest, there were 2 subsequent sudden deaths in patients treated with amiodarone, while 3 other patients received appropriate ICD discharges for VT during mean follow-up of 6.1 ± 4.0 years. Thus, only 10 of 15 patients were free of actually or potentially life-threatening arrhythmias during this relatively brief time frame.

The pathogenesis of life-threatening ventricular arrhythmias in HCM is likely multifactorial and risk stratification is acknowledged to be challenging, particularly in young patients.[163] Syncope and a family history of sudden death have long been considered markers of sudden death risk in young HCM patients.[162] Nonsustained VT on ambulatory ECG monitoring portends an increased risk of sudden death in adults with HCM.[164,165] The significance of this finding in children is less clear; one study involving 53 pediatric-aged HCM patients reported no apparent association between ambulatory VT and increased sudden death risk over a mean of 3 years of subsequent follow-up,[166] while a more recent retrospective evaluation of 99 children with HCM at our own institution with longer mean follow-up duration (4.8 years) showed VT detected on ambulatory monitoring to be highly predictive of future life-threatening events.[167]

Maki *et al.* performed a retrospective multivariate analysis to identify hemodynamic variables at rest and with exercise predictive of sudden death in 28 members of their 309 patient HCM study population followed over a mean of 9.4 years.[168] Higher resting left ventricular outflow tract gradient and blunted systolic blood pressure response to exercise independently predicted sudden death in the entire group. Of note, the mean age of 8 patients experiencing sudden death in the setting of exercise (28 years) was much lower than that of 20 patients who died suddenly at rest (47 years). Yetman *et al.* proposed that myocardial bridging of the left anterior descending coronary artery (LAD) could cause dynamic occlusion followed by myocardial ischemia. They demonstrated that among 36 children with HCM, 10 patients with myocardial LAD bridging had substantially higher incidences of VT (80% vs. 8%) and cardiac arrest (50% vs. 4%) than did those without myocardial bridging.[169] Aside from its novelty, this finding is of considerable interest because myocardial bridging is often amenable to surgical relief. However, the observation has been challenged by Mohiddin and colleagues, who argued that myocardial bridging

is merely a marker for severe left ventricular hypertrophy, and that it does not independently predict arrhythmias or sudden death in children with HCM.[170]

Recent studies have considered histopathologic and genetic factors as correlates of VT and sudden death in HCM. Varnava and coworkers demonstrated a greater degree of cardiac myocyte disarray in patients dying suddenly and aged younger than 21 years than in those dying of heart failure and at older ages. However, a history of nonsustained VT correlated directly with myocardial fibrosis and inversely with the extent of myocyte disarray among the 75 cases studied post-mortem.[171] Because of its reliance on substantial amounts of tissue for analysis, this approach is unlikely to achieve clinical applicability in HCM risk stratification. Among over 150 genetic mutations thus far linked to HCM, 4 affecting the cardiac β-myosin heavy chain and one involving the cardiac troponin T gene are considered particularly malignant with respect to their association with sudden life-threatening events. Ackerman and colleagues reasoned that screening for these particular mutations in HCM patients might be helpful in risk stratification. They found, however, that only 3 of the 293 unrelated HCM patients whom they tested were affected by any of the 5 mutations, notwithstanding that one-quarter of them had a family history of sudden death. The investigators concluded that this particular screening approach is unlikely to be of value in identifying patients at increased risk due to the marked genetic heterogeneity in HCM.[172]

VT associated with various other conditions

This section is intended to provide some elaboration and references with respect to selected conditions associated with VT in children as listed in Table 51-1. For the most part, there are no published outcome data relating specifically to pediatric VT in these conditions.

Myopathic processes

Inborn errors of fatty oxidation provide an example of congenital metabolic disorders featuring VT. In a series of 107 children with an inherited mitochondrial fatty acid β-oxidation disorder reported by Bonnet *et al.*, 24 had arrhythmias as the predominant presenting clinical abnormality, and 15 of these had VT described as polymorphic with degeneration to VF in 6 of 15. Mortality among the 24 arrhythmia patients was extremely high, with only 4 surviving beyond 2 years of follow-up.[173]

Corrado and colleagues recently presented data on noninvasively detected rhythm disturbances and echocardiographically determined ventricular function in 84 patients with Duchenne muscular dystrophy followed for a median of 76 months from age 18.6 ± 4.8 years. Among 81 patients undergoing Holter monitor recording, 19% had ventricular couplets and 7% had VT. There was 27% mortality in this group, and just over one-third of the deaths were described as sudden. The only variables found to predict mortality were the presence of at least six ventricular ectopic beats per hour on ambulatory monitoring, and left ventricular systolic dysfunction.[174]

Myotonic dystrophy has long been linked with arrhythmias and an increased risk of sudden death. Merino *et al.* performed invasive electrophysiologic testing, followed in most cases by transcatheter radiofrequency ablation, in 6 patients with myotonic dystrophy. All 6 were found to have BBRT, notwithstanding that 5 of 6 had no overt evidence of myocardial or valvular dysfunction.[78] A 17-year-old patient with myotonic dystrophy reported elsewhere had documented ILVT.[175]

Infiltrative or invasive heart muscle diseases

A number of years ago, Garson and coauthors generated considerable interest with their report of surgically resectable myocardial hamartomas serving as VT foci in infants.[176] Apart from a subsequent report of 2 cases from the Mayo Clinic,[177] however, this observation does not seem to have been reproduced at other centers. Indeed, primary cardiac tumours of most types are associated with ventricular arrhythmias[178,179] and should always be sought in newly diagnosed pediatric VT patients, but only rarely is an invasive lesion actually found to underlie ventricular ectopy.

Conduction abnormality

There is a well established association between complete heart block and VT which most often manifests as *torsades de pointes*.[180,181] Evidence obtained from animal heart block models indicates that bradycardia-mediated ventricular remodeling with downregulation of cardiac myocyte repolarizing currents likely underlies the predisposition to VT.[182,183]

Native structural congenital heart disease

There is an extensive literature documenting the association between mitral valve prolapse and various arrhythmias including VT. La Vecchia *et al.* performed extensive functional and anatomic studies in 28 consecutive adult patients with idiopathic VT. They echocardiographically diagnosed mitral valve prolapse in 7 (25%) of these patients, all of whom had VT of right bundle branch block QRS morphology, and all of whom had benign outcomes at mean follow-up of approximately 5 years.[184] Mechanisms by which the other lesions listed in Table 51-1 could predispose to ventricular arrhythmias include myocardial ischemia and imposition of anatomic or functional conduction barriers enabling development of reentrant circuits.

Drugs

Most drug-induced VT is due to cardiac potassium current inhibition, impaired cardiac myocyte repolarization and *torsades de pointes*.[185] This is certainly well demonstrated with respect to the "proarrhythmic" properties of many antiarrhythmic agents, as well as for certain antibiotics, antifungals, nonsedating antihistamines, and cisapride, all of which have been used extensively in children. There are, however, other pathways by which drugs can precipitate VT, including neurally mediated mechanisms that have been implicated with cocaine.[186]

The impact of newer interventions on pediatric VT outcomes

As indicated in the foregoing sections, the natural history of pediatric VT is often benign, particularly in most categories of primary VT. With increasing refinement in our understanding of the distinctions among various types of VT, physicians have a growing obligation to diagnose the cause and mechanism of VT with the greatest possible precision before recommending

therapy that can sometimes be more dangerous than the arrhythmia itself. Treatment should be directed at specific therapeutic endpoints, namely symptomatic relief or the prevention of adverse outcomes in settings of recognized risk. The temptation to aggressively treat asymptomatic patients with "ugly" VT on ECG or Holter tracings should be resisted when potentially life-threatening conditions such as PMVT, ARVD, and HCM have been convincingly excluded.

For many years, antiarrhythmic medications were the sole refuge for clinicians managing pediatric VT. A wide range of drugs has been used in pediatric VT with varying claims of success in trials that typically fail to meet currently accepted standards of randomization and control. Evaluation of these data is further complicated by small and heterogeneous patient populations, the subjective nature of symptomatic reporting, especially in children, and a lack of discrete differences in outcome between treated and untreated cases of many types of VT. Compelling exceptions to this general rule include the widely recognized beneficial effects of calcium channel blockers in ILVT[65,67,68] and beta blockers in PMVT,[88,90,91] although even these have not been subjected to rigorously controlled clinical trials. Antiarrhythmic agents continue to be a mainstay of pediatric VT therapy. Beyond beta blockers and calcium-channel blockers, medications most often found to be effective in chronic VT management are those belonging to Vaughan Williams classes 1c[187,188] and 3.[189,190]

Transcatheter radiofrequency ablation of supraventricular tachydysrhythmia substrates has gained widespread acceptance and achieved considerable success among pediatric cardiologists since 1990,[191] but experience with VT ablation in children remains limited and no large-scale outcome studies have been published as of this writing. A Dutch group recently reported their adult VT ablation results in a group of 122 men and 29 women aged 57 ± 16 years who were followed for an average of just under 3 years post-procedure. Their results are of interest because the 151 patients included 30 (20%) with primary VT and 32 (21%) with ARVD. Major procedural complications occurred in 7% of the patients, including death in 2%. The procedure was considered successful in 83% of cases, and VT subsequently recurred in 19% of successful cases and 64% of unsuccessful cases.[192]

Implantable cardioverter-defibrillator devices (ICD) undoubtedly represent the most significant advance in life-saving therapy for patients with dangerous ventricular arrhythmias,[193] and progressive miniaturization of these devices is making them increasingly accessible to infants and young children. ICD therapy is of clearly demonstrated benefit in high-risk HCM patients,[194] and there is a growing familiarity with its advantages and pitfalls in other conditions featuring life-threatening VT, such as ARVD[158] and PMVT.[86]

The earliest collected pediatric ICD experiences appeared in 1990.[195,196] Kron and colleagues' international survey identified just 40 patients aged <20 years who had undergone device implantation, with generally favorable results including 82% survival at 33 months of follow-up.[195] By 1993, the Pediatric Electrophysiology Society investigators were able to present 31 ± 23 months' worth of multicenter follow-up data on 125 of 177 identified patients who had received ICDs at ages ranging from 1.9 to 19.9 (mean 14.5) years. Indications for device implantation included resuscitated sudden cardiac death in 76%, drug refractory VT in 10%, and syncope with inducible sustained VT in 10%. The actuarial 5 year survival post-implantation was 85%, and ventricular dysfunction was the primary correlate of mortality among the 9 patients who died.[197] Hamilton and co-authors reported on the 5-year ICD experience of our own institution involving 11 patients aged 4–16 years in 1996. While relating a favorable experience overall including no mortality in follow-up ranging to 3.5 years, they also drew attention to the problem of inappropriate device discharges which occurred in 6 of the patients and were not completely controlled by the routine administration of beta blockers to prevent sinus tachycardia.[198] Recently, Love *et al.* reviewed the single center ICD experience of Children's Hospital, Boston, involving 81 implantation procedures up until December 1999, and focusing on the incidence of supraventricular tachycardias that could contribute to the occurrence of inappropriate device discharges in these patients. Of note, this series included a substantial number of adults, with patient ages ranging between 15 months and 48 years (median 16.5 years). In keeping with continuous improvements in device technology and physician experience in ICD management, there were only 2 deaths among 54 patients during a median follow-up duration of 38 months, and one of these deaths occurred in a patient who had refused replacement of a depleted generator. Three other patients underwent cardiac transplantation with ICD removal.[199] The increasingly routine use of ICDs in patients of all ages with life-threatening ventricular arrhythmias will almost certainly have a substantial impact on these patients' outcomes, with implications for life expectancy that are most profound in the pediatric population.

The Natural and Modified History of Congenital Heart Disease
Edited by Robert M. Freedom, Shi-Joon Yoo, Haverj Mikailian, William G.Williams

52

Professor Jane Somerville

Epilogue

The senior author of this work (RMF) and I have been friends for more than 30 years. We have witnessed most of the advances, developments and disasters in the understanding and management of congenital heart diseases. We have shared medical education at home and abroad, enjoying ourselves over the decades with the "world as our oyster," trying to make contributions and exchanging thoughts, some original, some crazy, some excellent and even useful as well as extraordinary. Despite differences in backgrounds and training we share the same sense of humor and have discovered similar perceptions of truth, facts and observations of the world of pediatric cardiology and the people players in it – good and bad. Our ideals have been maintained and goals remained the same. Bob has always been concerned with understanding the hearts, anatomy, angiography correlated with pathology and managing events in infants and children, particularly the complex anomalies. I, trained as an adult cardiologist, have been concerned with the outcomes of claimed surgical triumphs as their blemished futures unfolded, their care, diagnosis and the establishment of correct clinical services to give optimal medicine for life. Our aims were complementary. Neither of us became hooked on nomenclature nor embryological mythology. To us "what does it do?" was more important than "where does it come from?" All this and more was debated over many good meals, often with great wine and laughter. I am honoured to be "told" to write the last words in this encyclopedia of congenital heart disease.

Bob has always written papers and chapters and books, contributing so much to the dissemination of knowledge about congenital abnormalities of the heart as he swept in everybody's contributions, with full descriptions as shown so clearly in this book. There is no point in referencing this final chapter, all the relevant references are here. References for almost every condition and solution can be found somewhere in this tome. He has been my one encourager for ideas and "lateral" thoughts, constantly pressurizing me to write a book, which I would neither finish nor probably ever start. There was a suggestion we should combine in his last work and for a brief period it was agreed we would write together on "outcomes." He would bring knowledge and perspectives up to date, inserting his own views and I would address the long-term adult data and experience of clinical management and results of further surgery over decades. Our styles of thinking and writing are so different and with my lack of discipline and too many interests it did not happen.

This is Bob's book and that's how it's planned and executed. Yet the contributions of Shi-Joon Yoo, Haverj Mikailian and Bill Williams and the other contributors all add to the completion of this opus, and should not be underestimated or undervalued. I have followed the production with enthusiasm. Bob often showed and shared his contributions, always ignoring my criticisms and cries that this was not about "outcomes" and all attempts to change his English. What is there left to say about congenital heart disease after he has analysed all the referenced writing on all the anomalies which affect the heart and circulation at birth, and the evolution of management strategies witnessed to date?

What to call Chapter 52? I suggested Epilogue (not Epitaph!). He did not tell me. All I had was "please write it." Epilogue is, according to the *Oxford English Dictionary*, "the concluding part of a literary work," "a speech or short poem addressed to the spectators by one of the actors after the play is over." Epilogue is the correct title.

This book is "all ye know and all ye need to know" as Keats wrote when a medical student at Guy's Hospital (where I trained) and of greater importance where Blalock first visited across the ocean to speak of his success in treating cyanotic patients. I was a medical student, raw and playful. This initiated my intrigue and enthusiasm about congenital heart disease which has remained. Entranced and amazed by the "antics" of cardiac surgery, or was it surgeons, I was a "dresser" on the firm and subsequently the house surgeon to Sir Russell Brock. I so wanted to be a cardiac surgeon and part of all this excitement. It was one long thrill and many long days and nights of struggle for survival – the patient's and mine.

Finding my hands were not connected to my head, the need for reoperation, often so soon and very tedious long hours holding a retractor, I decided medical cardiology and observation of surgeons and their eccentricities in cardiac surgery could be a better professional path. Despite warnings of likely personal failure, cardiology was exciting as was the man of my "dreams" – both achieved.

This book is a whole "Ring Cycle" of congenital heart disease and pediatric cardiology explained in all its magnificence and weaknesses, available in one volume. It includes the triumphs of Wotan(s), the cardiac surgeons, the Niebelungs (pediatric cardiologists) developing over years into an organized and recognized group with a difficult start to establish themselves as a specific specialty, particularly in Europe. This development was inevitable since the need to treat infants and newborns, and now fetuses, with heart disease became clear. There are the strong Walkyrie (nurses) vital to success and their development into an influential force, and there were the naughty gnomes (guess who) and the occasional interventions of strong Brunhilde to solve, support and perhaps increase dissent. Like Wagner's

Ring, it tells of triumphs, greed, sadness, mistakes, misunderstandings and unexpected events and contains much of the author's philosophy and wisdom, as well as useful folklore. It is as amazing as Wagner, providing a chronicle of different eras, moods and thinking. Like Wagner the story is both simple, human and in parts complex and is equally compelling as the reality of what has been achieved over 50 years. The surgeons' triumphs have created the new medical community of grown up congenital hearts (GUCH) or "adults" as North America wishes to call them. "Adults" takes no account of the adolescents' care whose needs change as they "grow up." The management of the "transition" is fundamental. The arrival and advance of therapeutic medical interventions via catheter, to the Valhalle of pediatric cardiology will cause disruption to the surgeons but hopefully not destroy the practice and training of cardiac surgeons so needed for complex congenital heart disease, at least until successful prevention.

"This is not the end. It is not even the beginning of the end. It is perhaps the end of the beginning," so wrote Winston Churchill in 1942 and this applies to Chapter 52. What matters to us both is what happens to the patient and lesions over three score years and ten. Mostly we do not know but we are learning all the time as the new problems in the GUCH show themselves. The wide variety of abnormalities and innovative solutions by man have produced a constellation of different problems to be solved decades later.

There have been enough long-term survivors reaching adulthood over the last 40 years of surgical and medical progress to provide adequate information to demonstrate the need for specialist expertise to care for the long-term survivor, establishing the importance of informed medical care beyond childhood and pediatrics. Soon there will be more GUCHs than children with congenital heart disease in the population but fewer GUCH patients needing expert care since surgery helped so much. Total numbers do not reflect the medical needs of the GUCH community, although these are frequently used to demonstrate the growth and demands of the group. Freedom has profoundly influenced this development by supporting services for GUCH in Toronto General Hospital across the bridge and road; separate services, each with their autonomy, sharing surgeons and facilities but keeping healthily apart. Truly an exemplary development initiated by John Keith – a man of vision.

There are many long-term survivors with simple and severe lesions who have done well. Reparative surgery better performed in infants has evolved since the courageous and refined surgery by Dr Aldo Castaneda at the Boston Children's Hospital, who started his contributions to the surgical management of congenital heart disease where C Walton Lillehei took an immense risk using the mother as the bypass "machine" to repair a ventricular septal defect. Would the moralists and managers of today allow such spectacular risks which paved the way for the use and safety of cardiopulmonary bypass?

We know that radical repair of Fallot's tetralogy, the commonest cyanotic congenital heart disease has been a success over 40 years. Results are excellent with maintained long-term results with increasing "grandaddies." Large numbers of patients have been seen with good lives although but there are 10–15% with important residua. Discussions about pulmonary regurgitation, often inevitable to relieve the right ventricular tract obstruction, have occupied research and conference space for 30 years continuing with attractive solutions. Attention has been diverted to a small "layby" track with attention of a few to the dangers of widened QRS, frightening patients and physicians when QRS > 0.16. As part of a constellation of more important factors involving pulmonary regurgitation it can herald problems. It is the change that matters. There are many patients from yesteryears' surgery aging quietly, static with such findings and well. Attention is now returning to the straight path to concentrate on pulmonary valve leak and when it should be treated. Now we have nonsurgical means using Bonhoeffer's valve placed through a cardiac catheter. It is too soon to know if this new triumph will last. The life of the new valve will determine this but it does delay the first reoperation.

It could be as important as Ross's use of the cadaver aortic homograft to replace the diseased pulmonary valve placed in the right ventricular outflow for pulmonary atresia in 1966. An operation modified to treat many other forms of complex congenital heart diseases which has stood the text of time. A major advance for congenital heart diseases. Many factors influence longevity of homografts and the urgent need for something to prevent calcification and degeneration remains.

The dramatic reversal of the once disastrous fate of classic transposition with atrial septation by Mustard and Senning has seen many patients "grow up," still with problems yet often able to lead normal lives. Such problems are arrhythmias, baffle obstructions and systemic ventricular failure, the latter requiring a later arterial switch or cardiac transplantation to be salvaged. The long-term future of the "switched" transpositions for which the patients have to thank Adib Jatenes' ingenuity and courage in Sao Paulo has yet to unfold. What will happen to the neoaortic valve, the implanted coronary orifices and the multiple suture lines? So far it has been a real advance in restoring normality of circulation in patients with transposition and when applied to neonates as shown by Aldo Castaneda and which with Magdi Yacoub is now routine practice. The more recent evolution from physiological to anatomical repair of congenitally corrected transposition demands ingenious surgery; time will tell whether these new "double" switches are justified and when they should be undertaken.

Coarctation, one of the earliest lesions to have surgical repair, initiated by Clarence Crafoord, is a success story with many subsequent technical modifications which influence long-term complications and survival. Possibly now surgery may not be needed. Time will show. This simple condition provides the best example of diffuse "congenital cardiovascular disease" involving not only many other disorders of structure of the heart and valves but also the need to understand that there is congenital disease in conducting arteries and myocardium. This concept of structural congenital heart anomalies being part of congenital cardiovascular disease was proposed and demonstrated by a remarkable pathologist, Luis Becu in the early 1970s. Interest and rediscovery has been recently stimulated by Joe Perloff, a pioneer in GUCH management who must have felt, at times, that he cried in "the wilderness" to establish such services. The footprints of congenital cardiovascular disease give subtle signs or even dramatic events in adults. It is more frequent than realized and often undiscovered because of the shortage of informed and interested cardiac pathologists. The vital investigation of necropsy is often neglected in the millennium.

The consequences of failures in old Fontan patients, despite the occasional outstanding success, at least one grandfather known, provide extraordinary difficulties for those caring for GUCH patients. The misery and solutions for protein losing enteropathy, attrition of the long starved systemic ventricle, now

referred to as "restricted preload," dangerous and disasterous atrial arrhythmias confirm the imperfections of this once hailed answer for complex heart diseases. Without the efforts and ingenuity of Frances Fontan there might not have been the need for specialists in grown up congenital heart disease: cardiologists do not understand and do not want to understand the Fontan circulation. This does not prevent their attempts to manage and not refer. Those who pioneered the subspeciality of caring for outcomes are grateful to Fontan.

We have yet to learn the fate of long-term survivors of repaired hypoplastic hearts, cavopulmonary connections, interventional devices, new valves, and often new techniques. We need to know what is good and lasting. Already the study of GUCH patients calls for modification or even stopping some of the established techniques used in childhood. The solutions for the "ills" of the panacea may be more testing for surgeons and cardiologists than the primary intervention or replacement. "Total correction" is a dream but radical repair of many abnormalities has been an extraordinarily successful surgical endeavor. The continued scourge of arrthymias, progressive pulmonary vascular disease, destructive myocardial changes with terminal apoptosis, degeneration in biological and native valves still begs for solutions to better the outcomes for patients.

Pediatric cardiology, created by necessity to increase and strengthen success of cardiac surgery must change and we the "grown up cardiologists" must learn and care for the survivors. The specialty of congenital heart disease and its management has arrived at a point of maturity and understanding as shown with particular clarity by this book. It needs more time for cardiologist and patients to grow older with grace, style and more understanding before the true and complete final story of this Ring can be written.
